WORKS
ON
MEDICINE AND SCIENCE
PUBLISHED BY

JOHN CHURCHILL.

DR. GOLDSING BIRD, F.R.S.
THE DIAGNOSIS, PATHOLOGICAL INDICATIONS
AND TREATMENT OF URINARY DEPOSITS. With Thirty-
one Engravings on Wood. Post 8vo. cloth, 8s.

BY THE SAME AUTHOR.
ELEMENTS OF NATURAL PHILOSOPHY; being an
Experimental Introduction to the Study of the Physical Sciences.
8vo. cloth, 12s. 6d.

"We have great pleasure in welcoming a new edition of this excellent work, which we strongly recommended to our readers on its first appearance. We do not hesitate to pronounce it the best Manual of Natural Philosophy in our lan-
guage."—British and Foreign Medical Review.

DR. BUDD, F.R.S.
ON DISEASES OF THE LIVER; illustrated with
Coloured Plates and Engravings on Wood. 8vo. cloth, 14s.

"We cannot too strongly recommend the diligent study of this volume. The work cannot fail to rank the name of its author among the most enlightened pathologists and soundest practitioners of the day,"—Medico-Chirurgical Review.

DR. CARPENTER, F.R.S.
A MANUAL OF HUMAN PHYSIOLOGY; specially
designed for the Use of Students. With numerous Illustrations on
Steel and Wood. Fcap. 8vo. cloth, 12s. 6d.

BY THE SAME AUTHOR.
PRINCIPLES OF GENERAL AND COMPARATIVE
PHYSIOLOGY; intended as an Introduction to the Study of
Human Physiology, and as a Guide to the Philosophical Pursuit of
Natural History. Illustrated with numerous Figures on Copper and
Wood. The Second Edition. 8vo. cloth, 18s.

"I recommend to your perusal a work recently published by Dr. Carpenter. It has this advantage, it is very much up to the present state of knowledge on the subject. It is written in a clear style, and is well illustrated,"—Professor Sharpey's
Introductory Lecture.

BY THE SAME AUTHOR.
PRINCIPLES OF HUMAN PHYSIOLOGY. One thick
SIR ASTLEY COOPER, BART., F.R.S.

A TREATISE ON DISLOCATIONS AND FRAC-
TURES OF THE JOINTS. Edited by BRANSBY B. COOPER,
F.R.S. 8vo. cloth, 20s.

Sir Astley Cooper left very considerable additions in MS. for the ex-
press purpose of being introduced into this Edition.

"The present will be found a much more convenient edition of this invaluable
work than its predecessors. Although new matter and new illustrations have
been added, the price has been reduced from two guineas to twenty shillings.
After the fiat of the profession, it would be absurd in us to eulogize Sir Astley
Cooper's work on Fractures and Dislocations. It is a national one, and will prob-
ably subsist as long as English surgery."—Medico-Chirurgical Review.

BY THE SAME AUTHOR.

OBSERVATIONS ON THE STRUCTURE AND
DISEASES OF THE TESTIS. Illustrated with Twenty-four

Reduced from 3l. 3s. to 1l. 10s.

-------------------

MR. FERGUSSON, F.R.S.E.

A SYSTEM OF PRACTICAL SURGERY; with nu-
merous Illustrations on Wood. Second Edition. Fcap. 8vo. cloth,
12s. 6d.

"Professor Fergusson's work, we feel persuaded, will be as great a favourite as
it deserves, for it combines the powerful recommendations of cheapness and ele-
gance with a clear, sound, and practical treatment of every subject in surgical
science. The illustrations, by Bagg, are admirable—in his very best style."—
Edinburgh Journal of Medical Science.

-------------------

MR. FOWNES, PH. D., F.R.S.

A MANUAL OF CHEMISTRY; with numerous Illus-
trations on Wood. Fcap. 8vo. cloth, 12s. 6d.

"An admirable exposition of the present state of chemical science, simply and
clearly written, and displaying a thorough practical knowledge of its details, as
well as a profound acquaintance with its principles. The illustrations, and the
whole getting-up of the book, merit our highest praise."—British and Foreign
Medical Review.

BY THE SAME AUTHOR.

THE ACTONIAN PRIZE ESSAY OF 100 GUINEAS,
AWARDED BY THE COMMITTEE OF THE ROYAL INSTITUTION OF
GREAT BRITAIN.

CHEMISTRY; AS EXEMPLIFYING THE WISDOM AND
BENEFICENCE OF GOD. Post 8vo. cloth, 6s.
WITH A PREFACE BY PROFESSOR LIEBIG.

G. REMIGIUS FRESENIUS.

ELEMENTARY INSTRUCTION IN CHEMICAL ANALYSIS, as practised in the LABORATORY of GIESSIN. Edited by LLOYD BULLOCK.

QUALITATIVE; Second Edition. 8vo. cloth, 9s.

QUANTITATIVE; 8vo. cloth, 14s.

G. J. GUTHRIE, F.R.S.

THE ANATOMY OF THE BLADDER AND OF THE URETHRA, and the Treatment of the Obstructions to which these Passages are liable. Third Edition. 8vo. cloth, 5s.

BY THE SAME AUTHOR.

ON INJURIES OF THE HEAD AFFECTING THE BRAIN. 4to. boards, 6s.

"The great practical importance of those affections which constitute Mr. Guthrie's Treatise. A commentary on such a theme, written by a surgeon of experience and reputation, cannot fail to attract the attention of the profession."—British and Foreign Medical Review.

DR. GUY.

DR. MARSHALL HALL, F.R.S.

PRACTICAL OBSERVATIONS AND SUGGESTIONS IN MEDICINE. Post 8vo. cloth, 8s. 6d.

MR. HOOD.

ON THE DISEASES MOST FATAL TO CHILDREN, with Reference to the Propriety of Treating them as proceeding from Irritation, and not from Inflammation. Post 8vo. cloth, 6s.

"The views of Mr. Hood are, to a greater extent than is usually imagined, borne out by all the best late writers who have seen much practice among children. The work is purely a practical one, and is a valuable contribution to our knowledge."—Edinburgh Medical and Surgical Journal.

DR. HOPE, F.R.S.

A TREATISE ON THE DISEASES OF THE HEART AND GREAT VESSELS, and on the Affections which may be mistaken for them. With Plates. Third Edition. 8vo. cloth, 18s.
DR. HENNEN, F.R.S.

PRINCIPLES OF MILITARY SURGERY; comprising Observations on the Arrangement, Police, and Practice of Hospitals; and on the History, Treatment, and Anomalies of Variola and Syphilis. Illustrated with Cases and Dissections. Third Edition, with Life of the Author, by his Son, Dr. JOHN HENNEN. 8vo. boards, 16s.

MR. LAWRENCE, F.R.S.

A TREATISE ON RUPTURES. The Fifth Edition, considerably enlarged. 8vo. cloth, 16s.

"The peculiar advantage of the treatise of Mr. Lawrence is, that he explains his views on the anatomy of hernia and the different varieties of the disease in a manner which renders his book peculiarly useful to the student. It must be superfluous to express our opinion of its value to the surgical practitioner. As a treatise on hernia, presenting a complete view of the literature of the subject, it stands in the first rank."—Edinburgh Medical and Surgical Journal.

MR. LISTON, F.R.S.

PRACTICAL OR OPERATIVE SURGERY; with numerous Engravings on Wood. Fourth Edition. 8vo. cloth, 22s.

Extract from Preface.

"A new edition having been called for, the letter-press has been revised and corrected with care; extensive additions have been made, and many new wood-engravings added. These improvements, it is hoped, may render the work still more useful to surgical pupils, and better entitled to the patronage of the profession at large."

DR. HUNTER LANE, F.L.S., F.S.S.A.

A COMPRENDIUM OF MATERIA MEDICA AND PHARMACY; adapted to the London Pharmacopoeia, embodying all the New French, American, and Indian Medicines; and also comprising a Summary of Practical Toxicology. One neat pocket volume, cloth, 5s.

"Dr. Lane's volume is on the same general plan as Dr. Thompson's long known Conspectus; but it is much fuller in its details, more especially in the chemical department. It seems carefully compiled, is well suited for its purpose, and cannot fail to be useful.'"—British and Foreign Medical Review.

DR. LEE, F.R.S.

CLINICAL MIDWIFERY; with the Histories of Four Hundred Cases of Difficult Labour. Fcap. 8vo. cloth, 4s. 6d.

"The following Reports comprise the most important practical details of all the cases of difficult parturition which have come under my observation during the last fifteen years, and of which I have preserved written histories. They have now been collected and arranged for publication, in the hope that they may be found to illustrate, confirm, or correct the rules laid down by systematic writers, for the treatment of difficult labours, and supply that course of clinical instruction in midwifery, the want of which has been so often experienced by practitioners at the commencement of their career."—From Preface.
MR. LANGSTON PARKER.

THE MODERN TREATMENT OF SYPHILITIC DISEASES, both Primary and Secondary; comprehending the Improved Methods of Practice adopted in this Country and on the Continent, with numerous Formulae for the Preparation and Administration of the new Remedies; to which is added an Account of a Safe and Successful Mode of Treating Chronic, Constitutional, and Protracted Syphilis, by the Mercurial Vapour Bath. Second Edition, considerably enlarged. Post 8vo. cloth, 6s. 6d.

DR. MILLINGEN.

ON THE TREATMENT AND MANAGEMENT OF THE INSANE: with Considerations on Public and Private Lunatic Asylums. 18mo. cloth, 4s. 6d.

"Dr. Millingen, in one small pocket volume, has compressed more real solid matter than could be gleaned out of any dozen of octavos, on the same subject. We recommend this vade-mecum as the best thing of the kind we ever perused."
—Dr. Johnson's Review.

DR. PROUT, F.R.S.

ON THE NATURE AND TREATMENT OF STOMACH AND RENAL DISEASES; being an Inquiry into the Connexion of Diabetes, Calculus, and other Affections of the Kidney and Bladder with Indigestion. Fourth Edition. With Six Engravings. 8vo. cloth, 20s.

BY THE SAME AUTHOR.

CHEMISTRY, METEOROLOGY, AND THE FUNCTION OF DIGESTION, considered with reference to NATURAL THEOLOGY. Being a Third Edition, with much new matter, of the "Bridgewater Treatise." 8vo. cloth, 15s.

DR. RAMSbotham.

THE PRINCIPLES AND PRACTICE OF OBSTETRIC MEDICINE AND SURGERY, IN REFERENCE TO THE PROCESS OF PARTURITION. Illustrated with One Hundred and Ten Plates on Steel and Wood; forming one thick handsome volume. Second Edition. 8vo. cloth, 22s.

"The work of Dr. Ramsbotham may be described as a complete system of the principles and practice of midwifery; and the author has been at very great pains indeed to present a just and useful view of the present state of obstetrical knowledge. The illustrations are numerous, well selected, and appropriate, and engraved with great accuracy and ability. In short, we regard this work, between accurate descriptions and useful illustrations, as by far the most able work on the principles and practice of midwifery, that has appeared for a long time. Dr. Ramsbotham has contrived to infuse a larger proportion of common sense, and plain unpretending practical knowledge into his work, than is commonly found in works on this subject; and as such we have great pleasure in recommending it to the attention of obstetrical practitioners."—Edinburgh Medical and Surgical Journal.
DR. RANKING.

RESEARCHES AND OBSERVATIONS ON SCROFULOUS DISEASES. By J. G. LUGOL. Translated, with an Appendix. 8vo. cloth, 10s. 6d.

DR. RYAN.

THE UNIVERSAL PHARMACOPEIA; OR, A PRACTICAL FORMULARY of HOSPITALS, both BRITISH and FOREIGN. Third Edition, considerably enlarged. 32mo. cloth, 5s. 6d.

"This work is a conspectus of the best prescriptions of the most celebrated physicians and surgeons throughout the civilized world. It gives the doses and uses, the rules for prescribing, the actions of medicines on the economy, the various modes of administering them, and the principles on which they are compounded."

MR. SNELL, M.R.C.S.

A PRACTICAL GUIDE TO OPERATIONS ON THE TEETH. With Plates. 8vo. cloth, 8s.

"Those of our readers who practise in the department of surgery on which Mr. Snell’s essay treats will find some useful instructions on the mode of extracting teeth,“ &c. &c.—Medical Gazette.

DR. STEGGALL.

FOR MEDICAL AND SURGICAL EXAMINATION.

I.

A MANUAL FOR THE USE OF STUDENTS PREPARING FOR MEDICAL EXAMINATION; to which is now added, THE ELEMENTS OF BOTANY. Tenth Edition. 12mo. cloth, 8s. 6d.

II.

A MANUAL FOR THE COLLEGE OF SURGEONS; 12mo. cloth, 12s. 6d.

III.

GREGORY’S CONSPECTUS MEDICINÆ THEORETICÆ.
The First Part, containing the Original Text, with an Ordo Verborum and Literal Translation. 12mo. cloth, 10s.

IV.

THE FIRST FOUR BOOKS OF CELSUS. Containing the Text, Ordo Verborum, and Translation. 12mo. cloth, 8s.

* * The above two works comprise the entire Latin Classics required for Examination at Apothecaries’ Hall.

V.

A TEXT-BOOK OF MATERIA MEDICA AND THERAPEUTICS. 12mo. cloth, 7s.

VI.

FIRST LINES FOR CHEMISTS AND DRUGGISTS PREPARING FOR EXAMINATION AT THE PHARMACEUTICAL SOCIETY. 18mo. cloth, 3s. 6d.
THE MEDICAL REMEMBRANCER; OR, BOOK OF EMERGENCIES: in which are concisely pointed out the Immediate Remedies to be adopted in the First Moments of Danger from Poisoning, Drowning, Apoplexy, Burns, and other Accidents; with the Tests for the Principal Poisons, and other useful Information. Second Edition. 32mo. cloth, 2s. 6d.

"The plan of this little book is well conceived, and the execution corresponds thereunto. It costs little money, and will occupy little room; and we think no practitioner will regret being the possessor of what cannot fail, sooner or later, to be useful to him."—British and Foreign Medical Review.

J. STEPHENSON, M.D., & J. M. CHURCHILL, F.L.S.

MEDICAL BOTANY; OR, ILLUSTRATIONS AND DESCRIPTIONS OF THE MEDICINAL PLANTS OF THE PHARMACOPEIAS; comprising a popular and scientific Account of Poisonous Vegetables indigenous to Great Britain. New Edition, edited by GILBERT BURNETT, F.L.S., Professor of Botany in King's College. In three handsome royal 8vo. volumes, illustrated by Two Hundred Engravings, beautifully drawn and coloured from nature, cloth lettered, Six Guineas.

"The most complete and comprehensive work on Medical Botany."—Pharmaceutical Journal.

ALFRED S. TAYLOR, F.R.S.

A MANUAL OF MEDICAL JURISPRUDENCE.

Second Edition. Fcap. 8vo. cloth, 12s. 6d.

"We have the pleasure of meeting the accumulated stores of science and experience on this branch of knowledge, condensed and made accessible in this admirable volume. It is, in fact, not only the fullest and most satisfactory book we have ever consulted on the subject, but it is also one of the most masterly works we have ever perused."—Medical Gazette.

"The most elaborate and complete work that has yet appeared. It contains an immense quantity of cases, lately tried, which entitles it to be considered now what Beck was in its day."—Dublin Medical Journal.

"Mr. Taylor possesses the happy art of expressing himself on a scientific topic in intelligible language. The size of his Manual fits it to be a circuit companion. It is one of the most beautiful specimens of typography we ever had the pleasure—and it is a pleasure—of perusing."—Law Times.

BY A PRACTISING PHYSICIAN.

THE PRESCRIBER'S PHARMACOPEIA; containing all the Medicines in the London Pharmacopœia, arranged in Classes according to their Action, with their Composition and Doses. Third Edition. 32mo. cloth, 2s. 6d.

"Never was half-a-crown better spent than in the purchase of this 'Thesaurus Medicamini.' This little work, with our visiting-book and stethoscope, are our daily companions in the carriage."—Dr. Johnson's Review.
DISEASES OF THE SKIN.

By the same Author.

A PRACTICAL AND THEORETICAL TREATISE ON THE DIAGNOSIS, PATHOLOGY, AND TREATMENT OF CUTANEOUS DISEASES,

Arranged according to a Natural System of Classification, and preceded by an Outline of the Anatomy and Physiology of the Skin.

8vo. cloth, 10s. 6d.
THE ANATOMIST'S VADE MECUM:

A SYSTEM OF

HUMAN ANATOMY.

BY

ERASMUS WILSON.

WITH 186 ILLUSTRATIONS BY BAGG.

THIRD EDITION.

PREFACE

TO

SIR BENJAMIN COLLINS BRODIE, BART., F.R.S.

SERJEANT-SURGEON TO THE QUEEN,
MEMBER OF THE INSTITUTE OF FRANCE,

IN ADMIRATION OF THE HIGH ATTAINMENTS

WHICH HAVE JUSTLY PLACED HIM

IN THE FIRST RANK OF HIS PROFESSION,

THIS WORK

IS RESPECTFULLY INSCRIBED

BY

THE AUTHOR.
PREFACE.

The Preface to this little volume may be written in a few words. It first saw the light in the spring of 1840, and now, in the autumn of 1844, has reached its Third Edition. In this short period, less than five years, five thousand copies have been distributed among the Members of the Profession, many also taking their place in the libraries of Gentlemen, who, although not of the Profession, justly consider that some general knowledge of the structure of the body is an essential part of a liberal education. In the same period, a second edition of the work has appeared in America; and a translation, from the pen of Dr. Hollstein, has been completed in Berlin.

Thus the volume has quickly returned for review to the hands of the Author; and he trusts that an examination of the second and present editions will prove that he has not neglected this advantage. He has carefully corrected such omissions as may have occurred in the completion of a work on so extensive a subject; many parts which seemed scantily treated, he has entirely re-written; and he has endeavoured to give as full a description of every point in Anatomy, whether important or trivial, as is consistent with the limits and objects of a Practical Manual.

Two features in the Anatomist’s Vade Mecum appear to the Author to deserve notice:—the first relates to the labours of his professional brethren; the second to the illustrations contained in the work. On the first of these heads the Author begs to remark, that he considers it a duty, as well to them as to his readers and himself, to quote all recent observations and
discoveries in Anatomy which may have interest, and to give as complete an abstract of such discoveries as the scheme of the work will permit. By pursuing this plan, the Author trusts to distinguish his volume as the Record of the Profession at large, and not as the text-book merely of a particular school. And, in furtherance of his object, he has to request a continuance of those communications from scientific investigators, which have hitherto so materially aided him.

The woodcut Illustrations which accompany the Anatomist’s Vade Mecum have been increased with each edition. The number which appeared with the first was one hundred and fifty; with the second, one hundred and sixty-seven; and in the present they fall little short of two hundred. Several of the new figures are illustrative of General Anatomy, and, to insure their absolute correctness, have been drawn from the microscope by the Author himself, with the aid of the camera lucida. Figures 2, 3, and 4, showing the changes which occur during the development of bone; figures 47, 48, and 49, the minute anatomy of cartilage; and figure 80, the structure of the ultimate muscular fibril, are examples of such drawings. The structure exhibited in the latter figure formed the subject of a paper which was read before the Royal Society during the present year.

Upper Charlotte Street, Fitzroy Square,
November, 1844.

OSTEOLOGY.

The bones are the organs of support to the animal frame; they give firmness and strength to the entire fabric, afford points of connection to the numerous muscles, and bestow individual character upon the body. In the limbs they are hollow cylinders, admirably calculated by their conformation and structure to resist violence and support weight. In the trunk and head, they are flattened and arched, to protect cavities and provide an extensive surface for attachment. In some situations they present projections of variable length, which serve as levers; and in others are grooved into smooth surfaces, which act as pulleys for the passage of tendons. Moreover, besides supplying strength and solidity, they are equally adapted, by their numerous divisions and mutual apposition, to fulfil every movement which may tend to the preservation of the creature, or be conducive to his welfare.

According to the latest analysis by Berzelius, bone is composed of about one-third of animal substance, which is almost completely reducible to gelatine by boiling, and of two-thirds of earthy and alkaline salts. The special constituents are present in the following proportions:

Bones are divisible into three classes:—Long, flat, and irregular.

The Long bones are found principally in the limbs, and consist of a shaft and two extremities. The shaft is cylindrical or prismatic in form, dense and hard in texture, and hollowed in the interior into a medullary canal. The extremities are broad and expanded, to articulate with adjoining bones; and cellular or cancellous in internal structure. Upon the exterior of the bone are processes and rough surfaces for the attachment of muscles, and foramina for the transmission of vessels and nerves. The character of long bones is, therefore, their general type of structure and their divisibility into a central portion and extremities, and not so much their length; for there are some long bones, as the second phalanges of the toes, which are less than a quarter of an inch in length, and almost equal, and in some instances exceed, in breadth their longitudinal axis. The long bones are, the clavicle, humerus, radius and ulna, femur, tibia and fibula, metacarpal bones, metatarsal, phalanges and ribs.

Flat bones are composed of two layers of dense bone with an intermediate cellular structure, and are divisible into surfaces, borders, angles, and processes. They are adapted to enclose cavities; have processes upon their surface for the attachment of muscles; and are perforated for foramina, for the passage of nutrient vessels to their cells, and for the transmission of vessels and nerves. They articulate with long bones by means of smooth surfaces plated with cartilage, and with each other either by fibrous tissue, as at the symphysis pubis; or by suture, as in the bones of the skull. The two condensed layers of the bones of the skull are named, tables; and the intermediate cellular structure, diploë. The flat bones are the occipital, parietal, frontal, nasal, lachrymal, vomer, sternum, scapulae, and osse inominata.

The Irregular bones include all that remain after the long and the flat bones have been selected. They are essentially irregular in their form, in some parts flat, in others short and thick. In preceding editions of this work the short and thick bones were made a separate class under the name of short bones. This subdivision has been found to be disadvantageous, besides being arbitrary, and is, therefore, now omitted. Irregular bones are constructed on the same general principles with other bones; they have an exterior dense, and an interior more or less cellular. The bones of this class are, the temporal, sphenoid, ethmoid, superior maxillary, inferior maxillary, palate, inferior turbinate, hyoid, vertebrae, sacrum, coccyx, carpal and tarsal bones, and sesamoid bones, including the patella.

Structure of Bone.—Bone is a dense, compact, and homogeneous substance (basis substance) filled with minute cells, (corpuscles of Purkinje) which are scattered numerously through its structure. The basis substance of bone is subfibrous and obscurely lamellated, the lamellae being concentric in long and parallel in flat bones; it is traversed in all directions, but especially in the longitudinal axis, by branching and inosculating canals (Haversian canals) which give passage to vessels
and nerves, and in certain situations the lamellae separate from each other, and leave between them areolar spaces (cancelli) of various magnitude. The lamellae have an average diameter of \( \frac{1}{100} \) of an inch, and besides constituting the general structure of the basis substance, are collected concentrically around the Haversian canals, and form boundaries to those canals of about \( \frac{1}{250} \) of an inch in thickness. The number of lamellae surrounding each Haversian canal, is commonly ten or fifteen, and the diameters of the canals have a medium average of \( \frac{1}{100} \) of an inch. The cancelli of bone like its compact substance have walls which are composed of lamellae, and such is the similarity in structure of the parts of a bone, that the entire bone may be compared to an Haversian canal of which the medullary cavity is the magnified channel; and the Haversian canals may be likened to elongated and ramified cancelli. The Haversian canals are smallest near the

---

* Minute structure of bone, drawn with the microscope from nature, by Bagg. Magnified 300 diameters. 1. One of the Haversian canals surrounded by its concentric lamellae. The corpuscles are seen between the lamellae; but the calcigerous tubuli are omitted. 2. An Haversian canal with its concentric lamellae, Purkinjean corpuscles, and tubuli. 3. The area of one of the canals. 4. Direction of the lamellae of the great medullary canal. Between the lamellae at the upper part of the figure, several very long corpuscles with their tubuli are seen. In the lower part of the figure, the outlines of three other canals are given, in order to show their form and mode of arrangement in the entire bone.
surface of a bone, and largest near its centre, where they gradually merge into cancelli; by the frequent communications of their branches they form a coarse network in the basis substance.

The cells of bone, or corpuscles of Purkinje, are thickly disseminated through the basis substance; they are irregular in size and form, give off numerous minute branching tubuli which radiate from all parts of their circumference, and in the dried state of the bone contain merely the remains of membranous cells and some calcareous salts. In the living bone the cells and their tubuli are probably filled with a nutritive fluid holding calcareous salts in solution. The form of the cells is oval or round and more or less flattened, their long diameter corresponds with the long axis of the bone, and their tubuli cross the direction of the lamellæ and constitute a very delicate network in the basis substance by communicating with each other, and with the tubuli of neighbouring cells. The tubuli of the cells nearest the Haversian canals terminate upon the internal surface of those cavities. The size of the cells varies in extreme measurement from $\frac{1}{1000}$ to $\frac{1}{300}$ of an inch in their long diameter, an ordinary average being $\frac{1}{500}$; the breadth of the oval cells is about one half or one third their length, and their thickness one half their breadth. They are situated between the lamellæ, to which circumstance they owe their compressed form.

In the fresh state, bones are invested by a dense fibrous membrane, the periosteum, which covers every part of their surface with the exception of the articular extremities, the latter being coated by a thin layer of cartilage. The periosteum of the bones of the skull is termed pericranium; and the analogous membrane of external cartilages, perichondrium. Lining the interior of the medullary canal of long bones, the Haversian canals, the cells of the cancelli, and the cells of short, flat, and irregular bones, is the medullary membrane, which acts as an internal periosteum. It is through the medium of the vessels ramifying in these membranes that the changes required by nutrition occur in bones, and the secretion of medulla into their interior is effected. The medullary canal, Haversian canals and cells of long bones, and the cells of other bones, are filled with a yellowish oily substance, the medulla, which is contained in a loose areolar tissue formed by the medullary membrane.

Development of Bone.—To explain the development of bone it is necessary to inform the student that all organised bodies, whether belonging to the vegetable or the animal kingdom, are developed primordially from minute vesicles. These vesicles, or, as they are commonly termed, cells, are composed of a thin membrane containing a fluid or granular matter, and a small rounded mass, the nucleus, around which the cell was originally formed. Moreover, the nucleus generally contains one or more small round granules, the nucleolus or nucleoli. From cells having this structure all the tissues of the body are elaborated;

* Müller and Henle conceived that the bone cells and tubuli were the principal seat of the calcareous matter. Hence they have been named calcigerous cells and tubuli.
the ovum itself originally presented this simple form, and the embryo at an early period is wholly composed of such nucleated cells. In their relation to each other, cells may be isolated and independent, as is exemplified in the corpuscles of the blood, chyle and lymph; secondly, they may cohere by their surfaces and borders, as in the epidermis and epithelium; thirdly, they may be connected by an intermediate substance which is then termed intercellular, as in cartilage and bone; and fourthly, they may unite with each other in rows, and upon the removal by liquefaction of the adherent surfaces be converted into hollow tubuli. In the latter mode capillary vessels are formed, as also are the tubuli of nerve and muscular fibre. One of the properties of cells may also be adverted to in this place; it is that of reproducing similar cells in their interior. In this case the nucleoli become the nuclei of the secondary cells, and as the latter increase in size, the membrane of the primary or parent cell is lost.

Bone, in its earliest state, is composed of an assemblage of these minute cells, which are soft and transparent, and are disposed within the embryo in the site of the future skeleton. From the resemblance which the soft tissue bears to jelly, this has been termed the gelatinous stage of osteogenesis. As development advances, the cells, heretofore loosely collected together, become separated by the interposition of a transparent intercellular substance, which is at first fluid, but gradually becomes hard and condensed. The cartilaginous stage of osteogenesis is now established, and cartilage is shown to consist of a transparent matrix, having minute cells disseminated at pretty equal distances and without order through its structure. Coincident with the formation of cartilage is the development of vascular canals in its substance, the canals being formed by the union of the cells in rows, and the subsequent liquefaction of the adhering surfaces. The change which next ensues is the concentration of the vascular canals towards some one point; for example, the centre of the shaft in a long, or the mid-point of a flat bone, and here the punctum ossificationis or centre of ossification is established. What determines the vascular concentration now alluded to, is a question not easily solved, but that it takes place is certain, and the vascular punctum is the most easily demonstrable of all the phenomena of ossification.

During the formation of the punctum ossificationis, changes begin to be apparent in the cartilage cells. Originally they are simple nucleated cells (\(\frac{1}{30,000}\) to \(\frac{1}{20,000}\) of an inch in diameter), having a rounded form. As growth proceeds, they become elongated in their figure, and it is then perceived that each cell contains two and often three nucleoli around which smaller cells are in progress of formation. If we examine them nearer to the punctum ossificationis we find that the young or secondary cells have each attained the size of the parent cell (\(\frac{1}{20,000}\) of an inch), the membrane of the parent cell has disappeared, and the young cells are separated to a short distance by freshly effused intercellular substance. Nearer still to the punctum ossificationis a more remarkable change has ensued, the energy of cellule reproduction has
augmented with proximity to the ossifying point, and each cell in place of producing two, gives birth to four, five, or six young cells,

which rapidly destroy the parent membrane and attain a greater size ($\frac{1}{3}$ of an inch) than the parent cell, each cell being, as in the previous case, separated to a slight extent from its neighbour by inter-

* Figures illustrative of the development of bone; they are magnified 155 times, and drawn with the camera lucida. A. A portion of cartilage, the farthest removed from the seat of ossification, showing simple nucleated cells, having an ordinary size of $\frac{1}{3}$ of an inch, long diameter. B. The same cartilage nearer to the seat of ossification; each simple cell has produced two, which are a little larger than the cells in figure A.

† The same cartilage, still nearer the seat of ossification; each single cell of B has given birth to four, five, or six cells, which form clusters. These clusters become larger towards the right of the figure, and their cells more numerous and larger, $\frac{1}{5}$ of an inch, long diameter.
cellular substance. By one other repetition of the same process, each cell producing four or five, or six young cells, a cluster is formed, containing from thirty to fifty cells. These clusters lie in immediate relation with the punctum ossificationis; they are oval in figure (about $\frac{2}{3}$ in length by $\frac{1}{3}$ in breadth), and placed in the direction of the longitudinal axis of the bone. The cells composing the cluster lie transversely with regard to its axis. In the first instance they are closely compressed, but by degrees are parted by a thin layer of intercellular substance, and each cluster is separated from neighbouring clusters by a broader layer (about $\frac{1}{2}$ of inch) of intercellular substance. Such are the changes which occur in cartilage preparatory to the formation of bone.

Ossification is accomplished by the formation of very fine and delicate fibres within the intercellular substance: this process commences at the punctum ossificationis and extends from that point through every part of the bone, in a longitudinal direction in long, and in a radiated manner in flat bones. Starting from the punctum ossificationis, the fibres embrace each cluster of cells, and then send branches between the individual cells of each group. In this manner the network, characteristic of bone, is formed, while the cells by their conjunction

* The same cartilage at the seat of ossification; the clusters of cells are arranged in columns; the intercellular spaces between the columns being $\frac{1}{2}$ of an inch in breadth. To the right of the figure osseous fibres are seen occupying the intercellular spaces, at first bounding the clusters laterally, then splitting them longitudinally and encircling each separate cell. The greater opacity of the right hand border is due to a threefold cause, the increase of osseous fibres, the opacity of the contents of the cells, and the multiplication of oil globules. In the lower part of the figure some attempt has been made to show the texture of the cells.
constitute the permanent areolae and Haversian canals. With a high magnifying power, the delicate ossific fibres here alluded to are seen themselves to be composed of minute cells having an elliptical form and central nuclei. These cells attract into their interior the calcereous salts of the blood, and their nuclei become developed, as I believe, into the future corpuscles of Purkinje. It is possible also that some of the cartilage cells become corpuscles of Purkinje in the fully developed bone.

During the progress of the phenomena above described, the contents of the cells undergo certain changes. At first, their contents are transparent, then they become granular, and still later opaque, from the presence of amorphous matter mingled with nuclei, nucleoli, and the remains of secondary cells. In the latter state they also contain an abundance of minute oil-globules. These latter increase in size as the ossific changes advance, and in the newly formed osseous areolae they are very numerous and have attained the ordinary size of adipose cells.

Cartilaginification is complete in the human embryo at about the sixth week; and the first point of ossification is observed in the clavicle at about the seventh week. Ossification commences at the centre, and thence proceeds towards the surface; in flat bones the osseous tissue radiates between two membranes from a central point towards the periphery, in short bones from a centre towards the circumference, and in long bones from a central portion, diaphysis, towards a secondary centre, epiphysis, situated at each extremity. Large processes, as the trochanters, are provided with a distinct centre of development, which is named apophysis.

The growth of bone in length takes place at the extremity of the diaphysis, and in bulk by fresh deposition on the surface; while the medullary canal is formed and increased by absorption from within.

The period of ossification is different in different bones; the order of succession may be thus arranged:—

During the fifth week, ossification commences in the clavicle, lower jaw, and upper jaw.

During the sixth week, in the femur, humerus, tibia, radius, and ulna.

During the seventh and eighth weeks, in the fibula, frontal, occipital, sphenoid, ribs, parietal, temporal, nasal, vomer, palate, vertebrae, three first pieces of sacrum, malar, metacarpus, metatarsus, third phalanges of the hands and feet, and ilium.

During the third month, in the first and second phalanges of the hands and feet, lachrymal bone, and ischium.

During the fifth month, in the mastoid portion of the temporal, ethmoid, inferior turbinated, sternum, os pubis, and two last pieces of sacrum.

During the sixth month, in the body and odontoid process of the axis, and calcaneus.
The skeleton is divisible into: 1. The vertebral column or central axis. 2. The head and face, or superior development of the central axis. 3. The hyoid arch. 4. The thoracic arch and upper extremities. 5. The pelvic arch and lower extremities.
VERTEBRAL COLUMN.

The vertebral column is the first and only rudiment of internal skeleton in the lower Vertebrata, and constitutes the type of that great division of the animal kingdom. It is also the first developed portion of the skeleton in man, and the centre around which all the other parts are produced. In its earliest formation it is a simple cartilaginous cylinder, surrounding and protecting the primitive trace of the nervous system; but, as it advances in growth and organisation, it becomes divided into distinct pieces, which constitute vertebrae.

The vertebrae are divided into true and false. The true vertebrae are twenty-four in number, and are classified, according to the three regions of the trunk which they occupy, into cervical, dorsal, and lumbar. The false vertebrae consist of nine pieces united into two bones, the sacrum and coccyx. The arrangement of the vertebrae may be better comprehended by means of the accompanying table:—

Characters of a Vertebra.—A vertebra consists of a body, two laminae, a spinous process, two transverse processes, and four articular processes. The body is the solid part of the vertebra; and, by its articulation with adjoining vertebrae, gives strength and support to the trunk. It is flattened above and below, convex in front, and slightly concave behind. Its anterior surface is constricted around the middle, and pierced by a number of small openings which give passage to nutritious vessels. Upon its posterior surface is a single irregular opening, or several, for the exit of the venæ basis vertebrae.

The laminae commence upon the sides of the posterior part of the body of the vertebra by two pedicles; they then expand; and, arching backwards, enclose a foramen which serves for the protection of the spinal cord. The upper and lower borders of the laminae are rough for the attachment of the ligamenta subflava. The concavities above and below the pedicles are the intervertebral notches. The spinous process stands backwards from the angle of union of the laminae of the vertebra. It is the succession of these projecting processes along the middle line of the back, that has given rise to the common designation of the vertebral column, the spine. The use of the spinous process is for the attachment of muscles. The transverse processes project one at each side from the laminae of the vertebra; they are intended for the
attachment of muscles. The *articulare processes*, four in number, stand upwards and downwards from the laminae of the vertebra to articulate with the vertebra above and below.

*Cervical Vertebrae.*—In a cervical vertebra the body is smaller than in the other regions; it is thicker before than behind, broad from side to side, concave on the upper surface, and convex below; so that articulated, the vertebrae lock the one into the other. The *laminae* are narrow and long, and the included *spinal foramen* large and triangular. The *superior intervertebral notches* are slightly deeper than the inferior; the *inferior* being the broadest. The *spinous process* is short and bifid at the extremity, increasing in length from the fourth to the seventh. The *transverse processes* are also short and bifid, and deeply grooved along the upper surface for the cervical nerves. Piercing the base of the transverse process is the vertebral foramen† which gives passage to the vertebral artery and vein, and vertebral plexus of nerves. The transverse processes in this region, are formed by two small developments which proceed, the one from the side of the body, the other from the pedicle of the vertebra, and unite near their extremities to enclose the circular area of the vertebral foramen. The anterior of these developments is the rudiment of a cervical rib; and the posterior, the analogue of the transverse processes in the dorsal region. The extremities of these developments are the *anterior and posterior tubercles* of the transverse process. The *articulare processes* are oblique; the superior looking upwards and backwards; and the inferior, downwards and forwards.

There are three peculiar vertebrae in the cervical region:—The first or atlas; the second or axis; and the seventh or vertebra prominens.

The *Atlas* (named from supporting the head) is a simple ring of bone, without body and composed of arches and processes. The

---

* A central cervical vertebra, seen upon its upper surface. 1. The body, concave in the middle, and rising on each side into a sharp ridge. 2. The lamina. 3. The pedicle rendered concave by the superior intervertebral notch. 4. The bifid spinous process. 5. The bifid transverse process. The figure is placed in the concavity between the anterior and posterior tubercles, between the two processes which correspond with the rudimentary rib and the true transverse process. 6. The vertebral foramen. 7. The superior articular process, looking backwards and upwards. 8. The inferior articular process.

† Sometimes, as in a vertebra now before me, a small additional opening exists by the side of the vertebral foramen, in which case it is traversed by a second vein.
The posterior arch is longer and more slender than the anterior, and flattened from above downwards; at its middle is a rudimentary spinous process; and upon its upper surface, near the articular processes, a shallow groove \( \dagger \) at each side, which represents a superior intervertebral notch, and supports the vertebral artery previously to its passage through the dura mater, and the first cervical nerve. The intervertebral notches are peculiar from being situated behind the articular processes instead of before them, as in the other vertebrae. The transverse processes are remarkably large and long, and pierced by the foramen for the vertebral artery. The articular processes are situated upon the most bulky and strongest part of the atlas. The superior are oval and concave, and look inwards, so as to form a kind of cup for the condyles of the occipital bone, and are adapted to the nodding movements of the head; the inferior are circular, and nearly horizontal, to permit of the rotatory movements. Upon the inner face of the lateral mass which supports the articular processes, is a small tubercle at each side, to which the extremities of the transverse ligament are attached, a ligament which divides the ring of the atlas into two unequal segments; the smaller for receiving the odontoid process of the axis, and the latter to give passage to the spinal cord and its membranes.

The Axis (vertebra dentata) is so named from having a process upon which the head turns as on a pivot. The body is of large size, and supports a strong process, the odontoid, which rises perpendicularly from its upper surface. The odontoid process presents two articulating surfaces; one on its anterior face, to articulate with the anterior arch of the atlas; the other on its posterior face, for the transverse liga-

\* The upper surface of the atlas. 1. The anterior tubercle projecting from the anterior arch. 2. The articular surface for the odontoid process upon the posterior surface of the anterior arch. 3. \( \dagger \) This groove is sometimes converted into a foramen.
ment; the latter surface constricts the base of the process which has given rise to the term neck applied to this part. Upon each side of its apex is a rough depression, for the attachment of the alar ligaments; and running down from its base on the anterior surface of the body of the vertebra a vertical ridge, with a depression at each side for the attachment of the longus colli muscle. The laminae are large and strong, and unite posteriorly to form a long and bifid spinous process, which is concave beneath. The transverse processes are quite rudimentary, not bifid, and project only so far as to enclose the vertebral foramen, which is directed obliquely outwards instead of perpendicularly as in the other vertebrae. The superior articulating processes are situated upon the body of the vertebra on each side of the odontoid process. They are circular and nearly horizontal, having a slight inclination outwards. The inferior articulating processes look downwards and forwards, as do the same processes in the other cervical vertebrae. The superior intervertebral notch is remarkably shallow, and lies behind the articular process as in the atlas. The lower surface of the body is convex, and is received into the concavity upon the upper surface of the third vertebra.

The Vertebra prominens, or seventh cervical, approaches in character to the upper dorsal vertebrae. It has received its designation from having a very long spinous process, which is single and terminated by a tubercle, and forms a considerable projection on the back part of the neck; to the extremity of this process the ligamentum nuchae is attached. The transverse processes are but slightly grooved along the upper surface, have each a small foramen for the transmission of the vertebral vein, and present only a rudimentary bifurcation at their extremity. Sometimes the anterior tubercle represents a small but distinct rib.

Dorsal Vertebrae.—The body of a dorsal vertebra is as long from before backwards as from side to side, particularly in the middle of the dorsal region; it is thicker behind than before, and marked on each side by two half-articulating surfaces for the heads of two ribs. The

* A lateral view of the axis. 1. The body, the figure is placed on the depression which gives attachment to the longus colli. 2. The odontoid process. 3. The smooth facet on the anterior surface of the odontoid process which articulates with the anterior arch of the atlas; the facet for the transverse ligament is beneath No. 2, where the constriction called the neck of the odontoid process is seen; the bulk of the process between 2, 3, would represent its head. 4. The lamina. 5. The spinous process. 6. The transverse process pierced obliquely by the vertebral foramen. 7. The superior articular surface. 8. The inferior articular process.
pedicles are strong, and the laminae broad and thick; the spinal foramen small and round, and the inferior intervertebral notch of large size, the superior can scarcely be said to exist. The spinoous process is long, prismatic, directed very obliquely downwards, and terminated by a tubercle. The transverse processes are large and strong, and directed obliquely backwards. Upon the anterior and superior aspect of their summits is a small facet for the articulation of the tubercle of a rib. The articular processes are vertical, the superior facing directly backwards, and the inferior directly forwards.

The peculiar vertebrae in the dorsal region are the first, ninth, tenth, eleventh, and twelfth. The first dorsal vertebra approaches very closely in character to the last cervical. The body is broad from side to side, and concave above. The superior articular processes are oblique, and the spinoous process horizontal. It has an entire articular surface for the first rib, and a half surface for the second. The ninth dorsal vertebra has only one half articular surface at each side. The tenth has a single entire articular surface at each side. The eleventh and twelfth have each a single entire articular surface at each side; they approach in character to the lumbar vertebrae; their transverse processes are very short, trifid at their summits, and have no articulation with the corresponding ribs. The transverse processes of the twelfth dorsal vertebra are quite rudimentary, and its inferior articular processes look outwards.

Lumbar Vertebrae.—These are the largest pieces of the vertebral column. The body is broad and large, and thicker before than behind. The pedicles very strong; the laminae short, thick, and broad; the inferior intervertebral notches very large, and the spinal foramen large and oval. The spinoous process is thick and broad. The transverse processes (costiform processes) are slender, pointed, and directed only slightly backwards. The superior articular processes are concave, and

* A lateral view of a dorsal vertebra. 1. The body. 2. 2. Articular facets for the heads of ribs. 3. The pedicle. 4. The superior intervertebral notch. 5. The inferior intervertebral notch. 6. The spinoous process. 7. The extremity of the transverse process marked by an articular surface for the tubercle of a rib. 8. The two superior articular processes looking backwards. 9. The two inferior articular processes looking forwards.
look backwards and inwards; the inferior, convex, and look forwards and outwards. Projecting backwards and upwards from the superior articular process is a short and flattened tubercle or posterior transverse process, and in a strongly marked vertebra there is not unfrequently at the base of this a smaller tubercle which has a direction downwards. The last lumbar vertebra differs from the rest in having the body very much bevelled posteriorly, so as to be broad in front and narrow behind, and the transverse process thick and large.

**General Considerations.**—Viewed as a whole, the vertebral column represents two pyramids applied base to base, the superior being formed by all the vertebrae from the second cervical to the last lumbar, and the inferior by the sacrum and coccyx. Examined more attentively, it will be seen to be composed of four irregular pyramids, applied to each other by their smaller extremities and by their bases. The smaller extremity of the uppermost pyramid is formed by the axis, or second cervical vertebra; and its base, by the first dorsal. The second pyramid is inverted; having its base at the first dorsal, and the smaller end at the fourth. The third pyramid commences at the fourth dorsal, and gradually enlarges to the fifth lumbar. The fourth pyramid is formed by the sacrum and coccyx.

The *bodies* of the vertebrae are broad in the cervical region, narrowed almost to an angle in the middle of the dorsal, and again broad in the lumbar region. The *arches* are broad and imbricated in the cervical and dorsal regions, the inferior border of each overlapping the superior of the next; in the lumbar region an interval is left between them. A considerable interval exists between the cranium and atlas, and another between the last lumbar vertebra and sacrum.

The *spinous processes* are horizontal in the cervical, and become gradually oblique in the upper part of the dorsal region. In the middle of the dorsal region they are nearly vertical and imbricated, and towards its lower part assume the direction of the lumbar spines, which are quite horizontal. The *transverse processes* developed in

their most rudimentary form in the axis, gradually increase in length to the first dorsal vertebra. In the dorsal region they project obliquely backwards, and diminish suddenly in length in the eleventh and twelfth vertebrae where they are very small. In the lumbar region they increase to the middle transverse process, and again subside in length to the last.

The transverse processes consist essentially of two parts, the anterior of which in the dorsal region is the rib, while the posterior retains the name of the transverse process. In the cervical region these two elements are quite apparent, both by their different points of attachment to the vertebra, and by the vertebral foramen which divides them at their base. In the lumbar region the so-called transverse processes are, in reality, lumbar ribs, while the transverse processes will be found behind them in a rudimentary state, developed like the true transverse processes in the cervical region, from the superior articular processes. When the anterior and posterior transverse processes are examined in relation with each other, they will be observed to converge; and if the latter were prolonged they would unite as in the cervical region and enclose a foramen, or they would rest in contact as in the dorsal region, or become consolidated as in the formation of the sacrum. Moreover, the posterior transverse processes are directed upwards, and if they were prolonged, they would come into contact with a small tubercle which is found at the base of the posterior transverse process (in strongly marked vertebrae) in the vertebra above. This junction would form a posterior intervertebral foramen, as actually occurs in the sacrum. In brief, the lumbar vertebrae exhibit those transitional changes which are calculated, by an easy gradation, to convert separate vertebrae into a solid bone. The transverse processes of the eleventh and twelfth dorsal vertebrae are very interesting in a transcendental point of view, as exhibiting a tendency which exists obscurely in all the rest, namely, to trifurcate. Now, supposing these three branches to be lengthened in order to fulfill their purposes, the anterior would constitute the articulation or union with a rib, while the superior and inferior would join similar branches in the vertebra above and below, and so form the posterior intervertebral foramen.

The intervertebral foramina formed by the juxta-position of the notches, are smallest in the cervical region, and gradually increase to the last lumbar. On either side of the spinous processes, and extending the whole length of the column, is the vertebral groove, which is shallow and broad in the cervical, and deeper and narrower in the dorsal and lumbar regions. It lodges the principal muscles of the back.

Viewed from the side, the vertebral column presents several curves, the principal of which is situated in the dorsal region, the concavity looking forwards. In the cervical and lumbar regions the column is convex in front; and in the pelvis an anterior concave curve is formed by the sacrum and coccyx. Besides the antero-posterior curves, a
slight lateral curve exists in the dorsal region, having its convexity towards the right side.

Development.—The vertebrae are developed by three primary and five secondary centres or epiphyses. The primary centres are, one for each lamella, and one for the body; the epiphyses, one for the apex of the spinous process, one for that of each transverse process, and one for the upper and under surface of the body. Exceptions to this mode of development are met with in the atlas, axis, vertebra prominens, and lumbar vertebrae. The atlas has four centres: one for each lateral mass, one (sometimes two) for the anterior arch, and one for the centre of the posterior arch. The axis has five: one (sometimes two) for the body, two for the odontoid process, appearing side by side in its base, and one for each lamella. The vertebra prominens has two additional centres for the anterior or costal segments of the transverse processes, and the lumbar vertebrae two for the posterior segments of the transverse processes.

The primary centres of the vertebrae make their appearance during the seventh or eighth week of embryonic existence, the lamella being somewhat in advance of that for the body. From the former are produced the spinous, transverse, and articular processes, and the sides of the body; they unite, to complete the arch, one year after birth, and with the body during the fifth year. The epiphyses, for the extremities of the spinous and transverse processes, make their appearance at fifteen or sixteen, and become united between twenty and twenty-five. The epiphyses of the body are somewhat later in appearance, and are consolidated between the periods of twenty-five and thirty years of age.

The ossific centres for the lateral masses of the atlas appear at the same time with those of the other vertebrae; they unite posteriorly at the end of the second year, by the intervention of the centre for the posterior arch. The one or two centres of the anterior arch appear during the first year, and become consolidated with the lateral pieces during the fifth or sixth year. The axis develops its lateral pieces at the same time with the rest of the vertebrae; they join posteriorly soon after birth, and with the body during the fourth or fifth year. The centres for the body and odontoid process appear during the sixth month, and are consolidated during the third year. The body of the axis is more largely developed at birth than that of the other vertebrae. The costal segments of the vertebra prominens appear during the second month, and become united to the body at the fifth or sixth year. These processes sometimes remain permanently separate, and constitute a cervical rib. The transverse process of the first lumbar vertebra has sometimes a distinct centre, which may remain permanently separate, in that case forming a lumbar rib.

The ossification of the arches of the vertebrae commences from above, and proceeds gradually downwards; hence arrest of development gives rise to spina bifida, generally in the loins. Ossification of the bodies, on the contrary, commences from the centre, and proceeds
from that point towards the extremities of the column; hence imperfection of the bodies occurs either in the upper or lower vertebrae.

Attachment of muscles.—To the atlas are attached ten pairs of muscles; the longus colli, rectus anticus minor, rectus lateralis, rectus posticus minor, obliquus superior and inferior, splenius colli, levator anguli scapulae, first interspinales, and first intertransversales.

To the axis are attached twelve pairs, viz.: the longus colli, intertransversales, obliquus inferior, rectus posticus major, supraspinalis, interspinales, semi-spinalis colli, multifidus spine, levator anguli scapulae, splenius colli, transversalis colli, and scalenus posticus.

To the remaining vertebrae collectively, thirty-three pairs;—viz. posteriorly, the trapezius, latissimus dorsi, levator anguli scapulae, rhomboideus minor and major, serratus posticus superior and inferior, splenius, sacro-lumbalis, longissimus dorsi, spinalis dorsi, cervicalis ascendens, transversalis colli, trachelo-mastoideus, complexus, semi-spinalis dorsi and colli, multifidus spine, supraspinalis, interspinales, intertransversales, levatores costarum;—anteriorty, the rectus anticus major, longus colli, scalenus anticus and posticus, psoas magnus, psoas parvus, quadratus lumborum, diaphragm, obliquus internus and transversalis.

The Sacrum is a triangular bone, situated at the lower extremity of the vertebral column, and formed by the consolidation of five false vertebrae. It is divisible into an anterior and posterior surface, two lateral and a superior border, and an inferior extremity.

The anterior surface is concave, and marked by four transverse lines, which indicate its original constitution of five separate pieces. At the extremities of these lines, on each side, are the four anterior sacral foramina, which diminish in size from above downwards, and transmit the anterior sacral nerves. The projection of the superior piece is the sacro-vertebral angle or promontory.

The posterior surface is narrower than the anterior and convex. Upon the middle line is a rough crest formed by the rudiments of four spinous processes, the fifth remaining undeveloped and exposing the lower termination of the sacral canal. Immediately external to and parallel with the median crest, is a range of five small tubercles which represent the posterior transverse processes of the true vertebrae; beyond these is a shallow groove in which the four posterior sacral foramina open, and farther externally, a range of five tubercles corresponding with the anterior or costal transverse processes of the lumbar vertebrae. The lowest pair of the posterior transverse tubercles bound on each side the termination of the sacral canal, and send, each, a process downwards to articulate with the coccyx. The two descending processes are the sacral cornua. The posterior sacral foramina are smaller than the anterior, and transmit the posterior sacral nerves. Of the anterior transverse tubercles the first corresponds with the angle of the superior border of the bone; the second is small, and enters into the formation
of the sacro-iliac articulation; the third is large, and gives attachment to the oblique sacro-iliac ligament; the fourth and fifth are smaller, and serve for the attachment of the sacro-ischiatic ligaments. The lateral border of the sacrum presents superiorly a broad and ear-shaped (auricular) surface to articulate with the ilium; and inferiorly a sharp-edge, to which the greater and lesser sacro-ischiatic ligaments are attached. On the superior border, in the middle line, is an oval articular surface, which corresponds with the under part of the body of the last lumbar vertebra; and on each side, a broad triangular surface which supports the lumbo-sacral nerve and psoas magnus muscle. Immediately behind the vertebral articular surface is the triangular entrance of the sacral canal; and on each side of this opening an articular process, which looks backwards and inwards, like the superior articular processes of the lumbar vertebrae. In front of each articular process is an intervertebral notch. The inferior extremity of the bone presents a small oval surface which articulates with the coccyx; and on each side a notch, which, with a corresponding notch in the upper border of the coccyx, forms the foramen for the transmission of the fifth sacral nerve.

The sacrum presents some variety in respect of curvature, and of the number of pieces which enter into its structure. The curve is often very slight, and is situated only near the lower part of the bone; while in other subjects it is considerable, and occurs at the middle of the sacrum. The sexual differences in the sacrum relate to its greater breadth, and the greater angle which it forms with the rest of the vertebral column in the female, rather than to any peculiarity in shape. It is sometimes composed of six pieces, more rarely of four, and occasionally the first and second pieces remain permanently separate.

One of the sacral cornua. 11. The notch which is converted into a foramen by the coccyx.
Development.—By twenty-one points of ossification; five for each of the three first pieces, viz. one for the body, one for each lateral portion, and one for each lamina; and three for each of the two last, namely, one for the body, and one for each lateral portion. In the progress of growth, and after puberty, fourteen epiphysal centres are added, namely, two for the surfaces of each body, one for each auricular surface, and one for the thin edge of each lateral border. Ossification begins in the bodies of the sacral pieces somewhat later than in those of the true vertebrae; the first three appearing during the eighth and ninth week, and the last two at about the middle of intra-uterine existence. Ossification of the lamellæ takes place during the interval between the sixtith and the ninth month. The epiphyses for the upper and under surface of the bodies are developed during the interval between the fifteenth and eighteenth year; and for the auricular and marginal piece, after twenty. The two lower vertebral pieces, although the last to appear, are the first to be completed (between the fourth and fifth year), and to unite by their bodies. The union of the bodies takes place from below upwards, and finishes between the twenty-fifth and the thirtieth year, with the first two pieces.

Articulations.—With four bones; the last lumbar vertebra, os sacrum, and coccyx.

Attachment of Muscles.—To seven pairs; in front the pyriformis, on the side the coccygeus, and behind the gluteus maximus, latissimus dorsi, longissimus dorsi, sacro-lumbalis, and multifidus spinae.

The Coccyx (ξόκυξ cuckoo, from resembling a cuckoo’s beak) is composed of four small pieces, which form the caudal termination of the vertebral column. The superior piece is broad, and expands laterally into two transverse processes; it is surmounted by an oval articular surface and two cornua, the former to articulate with the apex of the sacrum, and the latter with the sacral cornua. The lateral wings sometimes become connected with the sacrum, and convert the notches for the fifth pair of sacral nerves into foramina. The remaining three pieces diminish in size from above downwards.

Development.—By four centres, one for each piece. Ossification commences in the first piece soon after birth; in the second, between five and ten years; in the third, between ten and fifteen; and in the fourth between fifteen and twenty. The pieces unite at an earlier period than the bodies of the sacrum, the two first pieces first, then the third and fourth, and lastly the second and third. Between forty and sixty years, the coccyx becomes consolidated with the sacrum; this event taking place later in the female than in the male.

Articulations.—With the sacrum.

Attachment of Muscles.—To three pairs, and one single muscle: gluteus maximus, coccygeus, posterior fibres of the levator ani, and sphincter ani.
The skull, or superior expansion of the vertebral column, is divisible into two parts,—the cranium and the face; the former being adapted by its form, structure, and strength, to contain and protect the brain, and the latter the chief organs of sense.

The Cranium is composed of eight separate bones; viz. the
- Occipital,
- Two temporal,
- Two parietal,
- Sphenoid,
- Frontal,
- Ethmoid.

Occipital Bone.—This bone is situated at the posterior part and base of the cranium. It is trapezoid in figure, and divisible into two surfaces, four borders, and four angles.

External Surface.—Crossing the middle of the bone transversely, from one lateral angle to the other, is a prominent ridge, the superior

The basilar process. 12, 12. The rough projections into which the odontoid ligaments are inserted.
curved line. In the middle of the ridge is a projection, called the external occipital protuberance; and descending from it a small vertical ridge, the spine. Above and below the superior curved line the surface is rough, for the attachment of muscles. About three-quarters of an inch below this line is another transverse ridge, the inferior curved line, and, beneath the latter, the foramen magnum. On each side of the foramen magnum, nearer to its anterior than its posterior segment, and encroaching somewhat upon the opening, is an oblong articular surface, the condyle, for articulation with the atlas. The condyles approach towards each other anteriorly, and their articular surfaces look downwards and outwards. Directly behind each condyle is an irregular fossa, and a small opening the posterior condyloid foramen, for the transmission of a vein to the lateral sinus. In front of the condyle is the anterior condyloid foramen, for the hypoglossal nerve; and on the outer side of each condyle a projecting ridge, the transverse process, excavated in front by a notch which forms part of the jugular foramen. In front of the foramen magnum is a thick square mass, the basilar process, and in the centre of the basilar process a small tubercle for the attachment of the superior and middle constrictor muscles of the pharynx.

**Internal Surface.**—Upon the internal surface is a crucial ridge, which divides the bone into four fossae; the two superior or cerebral fossae lodging the posterior lobes of the cerebrum; and the two inferior or cerebellar, the lateral lobes of the cerebellum. The superior arm of the crucial ridge is grooved for the superior longitudinal sinus, and gives attachment to the falx cerebri; the inferior arm is sharp and prominent, for the attachment of the falx cerebelli, and slightly grooved, for the two occipital sinuses. The transverse ridge gives attachment to the tentorium cerebelli, and is deeply grooved, for the lateral sinuses. At the point of meeting of the four arms, is a projection, the internal occipital protuberance, which corresponds with the similar process situated upon the external surface of the bone. The convergence of the four grooves forms a slightly depressed fossa, upon which rests the torcular Herophili. In the centre of the basilar portion of the bone is the foramen magnum, oblong in form, and larger behind than before, transmitting the spinal cord, spinal accessory nerves, and vertebral arteries. Upon the lateral margins of the foramen magnum are two rough eminences, which give attachment to the odontoid ligaments, and immediately above these the openings of the anterior condyloid foramina. In front of the foramen magnum is the basilar process, grooved on its surface, for supporting the medulla oblongata, and along each lateral border, for the inferior petrosal sinuses. On each side of the foramen magnum is a groove, for the termination of the lateral sinus; a smooth surface, which forms part of the jugular fossa; and a projecting process which divides the two, and is called the jugular eminence. Into the jugular fossa will be seen opening the posterior condyloid foramen.

The superior borders are very much serrated, and assist in forming
the lambdoidal suture; the inferior are rough, but not serrated, and articulate with the mastoid portion of the temporal bone by means of the additamentum suturee lambdoidalis. The jugular eminence and the side of the basilar process articulate with the petrous portion of the temporal bone, and the intermediate space, which is irregularly notched, forms the posterior boundary of the jugular foramen, or fora-

men lacerum posterius.

The angles of the occipital bone are the superior, inferior, and two lateral. The superior angle is received into the interval formed by the union of the posterior and superior angles of the parietal bones, and corresponds with that portion of the fetal head which is called the posterior fontanelle. The inferior angle is the articular extremity of the basilar process. The lateral angles at each side project into that

The anterior inferior angle. 8. The posterior inferior angle.
superior border is straight, to articulate with its fellow of the opposite side. The inferior border is arched and thin, to articulate with the temporal bone. The anterior border is concave, and the posterior somewhat convex.

_External Surface._—Crossing the bone in a longitudinal direction from the anterior to the posterior border, is an arched line, the _temporal ridge_, to which the temporal fascia is attached. In the middle of this line, and nearly in the centre of the bone, is the projection called the _parietal eminence_, which marks the centre of ossification. Above the temporal ridge the surface is rough, and covered by the aponeurosis of the occipito-frontalis; below the ridge the bone is smooth (_planum semicirculare_) for the attachment of the fleshy fibres of the temporal muscle. Near the superior border of the bone, and at about one-third from its posterior extremity, is the _parietal foramen_, which transmits a vein to the superior longitudinal sinus. This foramen is often absent.

_Fig. 14.*_

The anterior inferior angle of the bone, on which is seen the groove for the trunk of the _arteria meningea media_. 8. The posterior inferior angle, upon which is seen a portion of the groove for the lateral sinus.
completed by the opposite parietal bone, which serves to contain the
superior longitudinal sinus. Some slight pits are also observable near
this groove, which lodge the glandulae Pacchioni.

The anterior inferior angle is thin and lengthened, and articulates
with the greater wing of the sphenoid bone. Upon its inner surface
it is deeply channelled by a groove for the trunk of the arteria menin-
gea media. This groove is frequently converted into a canal. The
posterior inferior angle is thick, and presents a broad and shallow
groove for the lateral sinus.

Development.—By a single centre. Ossification commences at the
parietal eminence at the same time with the bodies of the vertebrae.

Articulations.—With five bones; with the opposite parietal bone,
the occipital, frontal, temporal, and sphenoid.

Attachment of Muscles.—To one only,—the temporal. The occi-
pio-frontalis glides over its upper surface.

FRONTAL BONE.—The frontal bone bears some resemblance in form
to the under valve of a scallop shell. It is situated at the anterior
part of the cranium, forming the forehead, and assists in the construc-
tion of the roof of the orbits and nose. Hence it is divisible into a
superior or frontal portion, and an inferior or orbito-nasal portion.
Each of these portions presents for examination an external and inter-
nal surface, borders, and processes.

External Surface.—At about the middle of each lateral half of the
frontal portion is a projection, the frontal eminence. Below these points
are the superciliary ridges, large towards their inner termination, and
becoming gradually smaller as they arch outwards; they support the
eyebrows. Beneath the superciliary ridges are the sharp and prominent
arches which form the upper margin of the orbits, the supra-orbi-
tal ridges. Externally the supra-orbital ridge terminates in the external
angular process, and internally in the internal angular process; at
the inner third of this ridge is a notch, sometimes converted into a fo-
ramen, the supra-orbital notch, which gives passage to the supra-orbi-
tal artery, veins, and nerve. Between the two superciliary ridges is a
rough projection, the nasal tuberosity; this portion of the bone denotes
by its prominence the situation of the frontal sinuses. Extending
upwards and backwards from the external angular process is a sharp
ridge, the commencement of the temporal ridge, and beneath this a
depressed surface that forms part of the temporal fossa.

The orbito-nasal portion of the bone consists of two thin processes,
the orbital plates, which form the roof of the orbits, and of an inter-
vening notch which lodges the ethmoid bone, and is called the ethmoi-
dal fissure. The edges of the ethmoidal fissure are hollowed into cavities,
which, by their union with the ethmoid bone, complete the ethmoidal
cells; and, crossing these edges transversely, are two small grooves,
sometimes canals, which open into the orbit by the anterior and posterior
ethmoidal foramina. At the anterior termination of these edges are
the irregular openings which lead into the frontal sinuses; and be-
tween the two internal angular processes, is a rough excavation which receives the nasal bones, and a projecting process, the nasal spine. Upon each orbital plate, immediately beneath the external angular process, is a shallow depression which lodges the lachrymal gland;

**Fig. 15.**

and beneath the internal angular process a small pit, sometimes a tubercle to which the cartilaginous pulley of the superior oblique muscle is attached.

**Internal Surface.**—Along the middle line of this surface is a grooved ridge, the edges of the ridge giving attachment to the falx cerebri and the groove lodging the superior longitudinal sinus. At the commencement of the ridge is an opening, sometimes completed by the ethmoid bone, the foramen cecum. This opening lodges a process of the dura mater, and occasionally gives passage to a small vein which communicates with the nasal veins. On each side of the vertical ridge are some slight depressions which lodge the glandulae Pacchioni, and on the orbital plates a number of irregular pits called digital fossæ.

The supra-orbital notch for the transmission of the supra-orbital nerve and artery; in the figure it is almost converted into a foramen by a small spiculum of bone. 7. The nasal tuberosity; the swelling around this point denotes the situation of the frontal sinuses. 8. The temporal ridge commencing from the external angular process (4). The depression in which the figure 8 is situated is a part of the temporal fossa. 9. The nasal spine.
which correspond with the convolutions of the anterior lobes of the cerebrum. The *superior border* is thick and strongly serrated, bevelled at the expense of the internal table in the middle, where it rests

upon the junction of the two parietal, and at the expense of the external table, on each side, where it receives the lateral pressure of those bones. The *inferior border* is thin, irregular, and squamous, and articulates with the sphenoid bone.

**Development.**—By two centres, one for each lateral half. Ossification begins in the orbital arches, somewhat before the vertebrae. The two pieces are separate at birth, and unite by suture during the first year, the suture sometimes remaining permanent through life. The frontal sinuses make their appearance during the first year, and increase in size until old age.

* The internal surface of the frontal bone; the bone is raised in such a manner as to show the orbito-nasal portion. 1. The grooved ridge for the lodging of the superior longitudinal sinus and attachment of the falx. 2. The foramen cecum. 3. The superior or coronal border of the bone; the figure is situated near that part which is bevelled at the expense of the internal table. 4. The inferior border of the bone. 5. The orbital plate of the left side. 6. The cellular border of the ethmoidal fissure. The foramen cecum (2) is seen through the ethmoidal fissure. 7. The anterior and posterior ethmoidal foramina; the anterior is seen leading into its canal. 8. The nasal spine. 9. The depression within the external angular process (12) for the lachrymal gland. 10. The depression for the pulley of the superior oblique muscle of the eye; immediately to the left of this number is the supra-orbital notch, and to its right the internal angular process. 11. The opening leading into the frontal sinuses. 12. The same parts are seen upon the opposite side of the figure.
Articulations.—With twelve bones; the two parietal, the sphenoid, ethmoid, two nasal, two superior maxillary, two lacrymal, and two malar.

Attachment of muscles.—To two pairs; corrugator supercilii, and temporal.

Temporal Bone.—The temporal bone is situated at the side and base of the skull, and is divisible into a squamous, mastoid, and petrous portion.

The Squamous portion, forming the anterior part of the bone, is thin, translucent, and contains no diploe. Upon its external surface it is smooth, to give attachment to the fleshy fibres of the temporal muscle, and has projecting from it an arched and lengthened process, the zygoma. Near the commencement of the zygoma upon its lower border, is a projection called the tubercle, to which is attached the external lateral ligament of the lower jaw, and

TEMPORAL BONE.

continued horizontally inwards from the tubercle a rounded eminence, the *eminentia articularis*. The process of bone which is continued from the tubercle of the zygoma into the eminentia articularis is the *inferior root* of the zygoma. The *superior root* is continued upwards from the upper border of the zygoma, and forms the posterior part of the temporal ridge, serving by its projection to mark the division of the squamous from the mastoid portion of the bone; and the *middle root* is continued directly backwards, and terminates abruptly at a narrow fissure, the fissura Glaseri. The *internal surface* of the squamous portion is marked by several shallow fossæ, which correspond with the convolutions of the cerebrum, and by a furrow for the posterior branch of the artæ meningæ media. The *superior*, or *squamous border*, is very thin, and bevelled at the expense of the inner surface, so as to overlap the lower and arched border of the parietal bone. The *inferior border* is thick and dentated to articulate with the spinous process of the sphenoid bone.

The *Mastoid portion* forms the posterior part of the bone; it is thick, and hollowed between its tables into a loose and cellular diploe. Upon its *external surface* it is rough for the attachment of muscles, and contrasts strongly with the smooth and polished-like surface of the squamous portion; every part of this surface is pierced by small foramina, which give passage to minute arteries and veins; one of these openings, oblique in its direction, of large size, and situated near the posterior border of the bone, the *mastoid foramen*, transmits a vein to the lateral sinus. This foramen is not unfrequently situated in the occipital bone. The inferior part of this portion is round and expanded, the *mastoid process*, and excavated in its interior into numerous cells, which form a part of the organ of hearing. In front of the mastoid process, and between the superior and middle roots of the zygoma, is the large oval opening of the *meatus auditorius externus*, surrounded by a rough lip, the *processus auditorius*. Directly to the inner side, and partly concealed by the mastoid process, is a deep groove, the *digastric fossa*; and a little more internally the *occipital groove*, which lodges the occipital artery. Upon its *internal surface* the mastoid portion presents a broad and shallow groove (*fossa sigmoidea*) for the lateral sinus, and terminating in this groove the internal opening of the mastoid foramen. The *superior border* of the mastoid portion is dentated; and its posterior border thick and less serrated for articulation with the inferior border of the occipital bone.

The *meatus auditorius externus* is a slightly curved canal, somewhat more than half an inch in length, longer along its lower than its upper wall, and directed obliquely inwards and forwards. The canal is narrower at the middle than at each extremity, is broadest in its horizontal diameter, and terminates upon the outer wall of the tympanum by an abrupt oval border. Within the margin of this border is a groove for the insertion of the membrana tympani.

The *Petrosus portion* of the temporal bone is named from its extreme
hardness and density. It is a three-sided pyramid, projecting horizontally forwards into the base of the skull, the base being applied against the internal surface of the squamous and mastoid portions, and the apex being received into the triangular interval between the spinous process of the sphenoid and the basilar process of the occipital bone. For convenience of description it is divisible into three surfaces—anterior, posterior, and basilar; and three borders—superior, anterior, and posterior.

Surfaces.—The anterior surface, forming the posterior boundary of the middle fossa of the interior of the base of the skull, presents for examination from base to apex, first, an eminence caused by the projection of the perpendicular semicircular canal; next, a groove leading to an irregular oblique opening, the hiatus Fallopii, for the transmission of the petrosal branch of the Vidian nerve; thirdly, another and smaller oblique foramen, immediately beneath the preceding, for the passage of the nervus petrosus superficialis minor, a branch of Jacobson’s nerve; and lastly, a large foramen near the apex of the bone, the termination of the carotid canal.

The posterior surface forms the front boundary of the posterior fossa of the base of the skull; near its middle is the oblique entrance

The petrous portion. 4. The groove for the posterior branch of the arteria meningea media. 5. The bevelled edge of the squamous border of the bone. 6. The zygoma. 7. The digastric fossa immediately internal to the mastoid process. 8. The occipital groove. 9. The groove for the lateral sinus. 10. The elevation upon the anterior surface of the petrous bone marking the situation of the perpendicular semicircular canal. 11. The opening of termination of the carotid canal. 12. The meatus auditortius internus. 13. A dotted line leads upwards from this number to the narrow fissure which lodges a process of the dura mater. Another line leads downwards to the sharp edge which conceals the opening of the aqueductus cochleae, while the number itself is situated on the bony lamina which overlies the opening of the aqueductus vestibuli. 14. The styloïd process. 15. The stylo-mastoid foramen. 16. The carotid foramen. 17. The jugular process. The deep excavation to the left of this process forms part of the jugular fossa, and that to the right is the groove for the eighth pair of nerves. 18. The notch for the fifth nerve upon the upper border of the petrous bone, near to its apex. 19. The extremity of the petrous bone which gives origin to the levator palati and tensor tympani muscles.
of the meatus auditorius internus. Above the meatus auditorius internus is a small oblique fissure, and a minute foramen; the former lodges a process of the dura mater, and the foramen gives passage to a small vein. Further outwards, towards the mastoid portion of the bone, is a small slit, almost hidden by a thin plate of bone; this is the aquaeductus vestibuli, and transmits a small artery and vein of the vestibule and a process of dura mater. Below the meatus, and partly concealed by the margin of the posterior border of the bone, is the aquaeductus cochlear, through which passes a vein from the cochlea to the internal jugular vein, and a process of dura mater.

The meatus auditorius internus is about one-third of an inch in depth, and pursues a slightly oblique course in relation to the petrous portion of the temporal bone, but a course directly outwards in relation to the cranium. At the bottom of the meatus, and upon its anterior aspect, is a reniform fossa, the concave border of which is directed towards the entrance of the meatus. The reniform fossa is divided into an upper and lower compartment by a sharp ridge, which is prolonged for some distance upon the anterior wall of the meatus and sometimes as far as its aperture; in either case it marks the situation of the two nerves, facial and auditory, which constitute the seventh pair, and enter the meatus. Along the convexity of the reniform fossa, and arranged in a curved line from above downwards, are four of five openings, the two upper ones being the largest, and occupying the superior compartment of the reniform fossa, and the two or three inferior ones, smaller than the upper, the inferior compartment. Behind the latter, at the distance of a line and a half, and on the posterior wall of the meatus is a cluster of three or four oblique openings, two of which are minute. The inferior and larger compartment of the reniform fossa presents a well-marked spiral groove, which commences on the convex border of the fossa, immediately below the line of openings above described, and, sweeping round the convexity of the inferior compartment, and becoming deeper as it proceeds, terminates by a small round aperture in the centre of the spire. The uppermost of the openings of the reniform fossa is the aperture of the aquaeductus Fallopian and gives passage to the facial nerve. The rest are cul de sacs, pierced at the bottom by a number of minute foramina for the passage of filaments of the vestibular nerve, while the cluster of three openings on the posterior wall of the meatus are intended for single filaments of the same nerve. The spiral groove corresponds with the base of the cochlea, and being pierced by a number of minute foramina for filaments of the cochlear nerve, is named tractus spiralis foraminulentus. The opening in the centre of the spiral impression leads into a canal which occupies the central axis of the modiolus, and is thence called tubulus centralis modioli.

The basilar surface is rough and irregular, and enters into the formation of the under surface of the base of the skull. Projecting downwards, near its middle, is a long sharp spine, the styloid process, occasionally connected with the bone only by cartilage and lost during
maceration, particularly in the young subject. At the base of this process is a rough sheath-like ridge, into which the styloid process appears implanted, the vaginal process. In front of the vaginal process is a broad triangular depression, the glenoid fossa, bounded in front by the eminentia articularis, behind by the vaginal process, and externally by the rough lip of the processus auditorius.

*Fig. 19.*

This fossa is divided transversely by the *glenoid fissure* (fissura Glaseri) which lodges the extremity of the processus gracilis of the malleus, and transmits the laxator tympani muscle, chorda tympani nerve, and anterior tympanic artery. The surface of the fossa in front of this fissure is smooth, to articulate with the condyle of the lower jaw; and that behind the fissure is rough, for the reception of a part of the parotid gland. At the extremity of the inner angle of the glenoid fossa is the foramen of the Eustachian tube; and separated from it by a thin lamella of bone, called *processus cochleariformis*, a small canal for the transmission of the tensor tympani muscle. Directly behind, and at the root of the styloid process, is the *stylo-mastoid foramen*, the opening of exit to the facial nerve, and of entrance to the stylo-mastoid artery. Nearer to the apex of the bone is a large oval

opening, the carotid foramen, the commencement of the carotid canal, which lodges the internal carotid artery and the carotid plexus. And between the stylo-mastoid and carotid foramen, in the posterior border, is an irregular excavation forming part of the jugular fossa for the commencement of the internal jugular vein. The proportion of the jugular fossa formed by the petrous portion of the temporal bone is very different in different bones; but in all, the fossa presents a vertical ridge to its inner side, which cuts off a small portion from the rest. The upper part of this ridge forms a spinous projection, which is called the jugular process, the groove to the inner side of the ridge lodges the eighth pair of nerves, and the lower part of the ridge is the septum of division between the jugular fossa and the carotid foramen. Upon this portion of the ridge near the posterior margin of the carotid foramen is a small opening leading into a canal, which transmits the tympanic branch of the glossopharyngeal nerve (Jacobson's nerve). Between the jugular fossa and the stylo-mastoid foramen is another small opening leading into the canal for the passage of the tympanic branch of the pneumogastric nerve.

Borders.—The superior border is sharp, and gives attachment to the tentorium cerebelli. It is grooved for the superior petrosal sinus, and near its extremity is marked by a smooth notch upon which reclines the fifth nerve.

The anterior border is grooved for the Eustachian tube, and forms the posterior boundary of the foramen lacerum basis cranii; by its sharp extremity it gives attachment to the tensor tympani and levator palati muscles. The posterior border is grooved for the inferior petrosal sinus, and excavated for the jugular fossa; it forms the anterior boundary of the foramen lacerum posterius.

Development.—By five centres; one for the squamous portion, one for the mastoid process, one for the petrous portion, one for the auditory process, which in the fetus is a mere bony ring, incomplete superiority, and serving for the attachment of the membrana tympani, annulus membranae tympani; and one for the styloid process. Osseification occurs in these pieces in the following order: in the squamous portion immediately after the vertebrae, then in the petrous, tympanic, mastoid, and styloid. The tympanic ring is united by its extremities to the squamous portion during the last month of intrauterine life; the squamous, petrous and mastoid portions are consolidated during the first year; and the styloid some years after birth. It not unfrequently happens that the latter remains permanently separate, or is prolonged by a series of pieces to the os hyoides, and so completes the hyoid arch. The subsequent changes in the bone are the increase of size of the glenoid fossa, the growth of the meatus auditorius externus, the leveling of the surfaces of the petrous portion and the development of mastoid cells. Traces of the union of the petrous with the squamous portion of the bone are usually perceptible in the adult.

Articulations.—With five bones; occipital, parietal, sphenoid, inferior maxillary and malar.
Attachment of Muscles.—To fourteen; by the squamous portion, to the temporal; by the zygoma, to the masseter; by the mastoid portion, to the occipito-frontalis, splenius capitis, sterno-mastoid, tracheo-mastoid, digastricus and retrahens aurem; by the styloid process, to the stylo-pharyngeus, stylo-hyoideus, stylo-glossus, and two ligaments, the stylo-hyoid and stylo-maxillary; and by the petrous portion, to the levator palati, tensor tympani, and stapediaus.

Sphenoid Bone.—The sphenoid (σφήν, a wedge) is an irregular bone situated at the base of the skull, wedged between the other bones of the cranium, and entering into the formation both of the cranium and face. It bears some resemblance in form to a bat with its wings extended, and is divisible into body, wings, and processes.

The body forms the central mass of the bone, from which the wings and processes are projected. From the upper and anterior part of the body extend on each side two small triangular plates,—the lesser wings; from either side and expanding laterally are the greater wings; proceeding backwards from the base of the greater wings, the spinous processes, and downwards, the pterygoid processes.

The body presents for examination a superior or cerebral surface, an antero-inferior surface, and a posterior surface.

Superior Surface.—At the anterior extremity of this surface is a small projecting plate, the ethmoidal spine, and spreading out on either side the lesser wings. Behind the ethmoidal spine in the middle line is a rounded elevation, the olivary process, which supports the commissure of the optic nerves, and on either side of the posterior margin of this process is a tubercle, the middle clinoid process. Passing outwards and forwards from the olivary process, are the optic foramina, which transmit the optic nerves and ophthalmic arteries. Behind the optic foramina are two sharp tubercles, the anterior clinoid processes, which are the inner terminations of the lesser wings. Beneath these processes, on the sides of the olivary process, are two depressions* for the last turn of the internal carotid arteries. Behind the olivary process is the sella turcica (ephippium), the deep fossa which lodges the pituitary gland and circular sinus; behind and somewhat overhanging the sella turcica, is a broad rough plate (dorsum ephippii), bounded at each angle by a tubercle, the posterior clinoid processes; and behind this plate an inclining surface (clivus Blumenbachii), which is continuous with the basilar process of the occipital bone. On either side of the sella turcica is a broad groove (carotid) which lodges the internal carotid artery, the cavernous sinus, and the orbital nerves. Immediately external to this groove, at the junction of the greater wings with the body, are four foramina; the first is a broad interval, the sphenoidal fissure, which separates the greater and lesser wings, and transmits the third, fourth, the three branches of the

* These depressions are occasionally, as in a skull before me, converted into foramina by the extension of a short bony pillar from the middle to the anterior clinoid process.
ophthalmic division of the fifth and the sixth nerves, and the ophthal-
mic vein. Behind and beneath this fissure is the foramen rotundum
for the superior maxillary nerve; and still farther back, in the base of
the spinous process, the foramen ovale for the inferior maxillary nerve,

arteria meningea parva, and nervus petrosus superficialis minor. Be-
hind the foramen ovale, near the apex of the spinous process, is the
foramen spinosum for the arteria meningea media.

Upon the antero-inferior surface of the sphenoid is a long flattened
spine or crest, the superior part of which, crista sphenoidalis, articulates
with the central lamella of the ethmoid, while the inferior part longer
and sharper, the rostrum sphenoidale, is intended to be inserted into
the sheath formed by the upper border of the vomer. On either side
of the crista sphenoidalis is an irregular opening leading into the

opticum. 8. The anterior clinoid process. 9. The groove by the side of the
sella turcica; for lodging the internal carotid artery, cavernous plexus, ca-
vernus sinus, and orbital nerves. 10. The sella turcica; the two tubercles in
front of the figure are the middle clinoid processes. 11. The posterior boundary
of the sella turcica; its projecting angles are the posterior clinoid processes.
The foramen rotundum. 15. The foramen ovale. 16. The foramen spinosum.
17. The angular interval which receives the apex of the petrous portion of the
temporal bone. The posterior extremity of the Vidian canal terminates at this
angle. 18. The spine of the spinous process; it affords attachment to the in-
ternal lateral ligament of the lower jaw. 19. The border of the greater wing
and spinous process, which articulates with the anterior part of the squamous
portion of the temporal bone. 20. The internal border of the spinous process,
which assists in the formation of the foramen lacerum basis cranii. 21. That
portion of the greater ala which articulates with the anterior inferior angle
of the parietal bone. 22. The portion of the greater ala which articulates with
the orbital process of the frontal bone.
Sphenoidal cells. The sphenoidal cells, which are absent in the young subject, are divided by a median septum which is continuous with the crista, and are partially closed by two thin plates of bone (frequently broken away), the sphenoidal spongy bones. On each side of the sphenoidal cells are the outlets of the optic foramina, sphenoidal fissures, and foramina rotunda, the lesser and greater wings; and below, the pterygoid processes. Upon the under surface of the body are two thin plates of bone (processus vaginales) proceeding from the base of the pterygoid process at each side and intended for articulation with the borders of the vomer. On each of these plates, close to the root of

Fig. 21.*

the pterygoid process, is a groove (sometimes a complete canal) converted into a canal by the palate bone, the pterygo-palatine canal for the pterygo-palatine artery; and traversing the roots of the pterygoid processes at their union with the body of the bone are the two pterygoid or Vidian canals which give passage to the Vidian nerve and artery at each side.

The posterior surface is flat and rough, and articulates with the basilar process of the occipital bone. In the adult, this union is usually completed by bone; from which circumstance the sphenoid, in conjunction with the occipital, is described by Soemmering and Meckel as a single bone, under the name of spheno-occipital. The posterior

surface is continuous on each side with the spinous process, and at the angle of union is the termination of the Vidian canal.

The lesser wings (processes of Inggrassias) are thin and triangular, the base being attached to the upper and anterior part of the body of the sphenoid, and the apex extended outwards, and terminating in an acute point. The anterior border is irregularly serrated, the posterior being free and rounded and received into the fissure of Sylvius of the cerebrum. The inner extremity of this border is the anterior clinoid process, which is supported by a short pillar of bone, giving attachment to a part of the common tendon of the muscles of the orbit. The lesser wing forms the posterior part of the roof of the orbit, and its base is traversed by the optic foramen.

The greater wings present three surfaces; a superior or cerebral, which forms part of the middle fossa of the base of the skull, an anterior surface which assists in forming the outer wall of the orbit, and an external surface divided into two parts by the pterygoid ridge. The superior part of the external surface enters into the formation of the temporal fossa, and the inferior portion forms part of the zygomatic fossa. The pterygoid ridge, dividing the two, gives attachment to the upper origin of the pterygoideus externus muscle.

The spinous processes project backwards at each side from the base of the greater wings of the sphenoid, and are received into the angular intervals between the squamous and petrous portions of the temporal bones. Piercing the base of each process is a large oval opening, the foramen ovale; nearer its apex a smaller opening, the foramen spinosum; and extending downwards from the apex a short spine, which gives attachment to the internal lateral ligament of the lower jaw and to the laxator tympani muscle. The external border of the spinous process is rough, to articulate with the lower border of the squamous portion of the temporal bone; the internal forms the anterior boundary of the foramen lacerum basis cranii, and is somewhat grooved for the reception of the Eustachian tube.

The pterygoid processes descend perpendicularly from the base of the greater wings, and form in the articulated skull the lateral boundaries of the posterior nares. Each process consists of an external and internal plate, and an anterior surface. The external plate is broad and thin, giving attachment, by its external surface, to the external pterygoid muscle, and by its internal surface to the internal pterygoid. This plate is sometimes pierced by a foramen, which is not unfrequently formed by a process of communication passing between it and the spinous process. The internal pterygoid plate is long and narrow, and terminated at its extremity by a curved hook, the hamular process, around which plays the tendon of the tensor palati muscle. At the base of the internal pterygoid plate is a small oblong depression, the sphenoid fossa, from which arises the circumflexus or tensor palati muscle. The interval between the two pterygoid plates is the pterygoid fossa; and the two plates are separated inferiorly by an angular notch (palatine) which receives the tuberosity, or pterygoid
process, of the palate bone. The anterior surface of the pterygoid process is broad near its base, and supports Meckel's ganglion. The base of the process is pierced by the Vidian canal.

Development.—By twelve centres; four for the body, viz. two for its anterior (spheno-orbital), and two for its posterior part (sphenotemporal); four for the four wings; two for the internal pterygoid plates, and two for the sphenoidal spongy bones. Ossification commences in the various pieces of the sphenoid in the following order:—greater alæ, at about the same time with the other bones of the cranium; lesser alæ, posterior body, at the end of the second month; anterior body at the end of the third; internal pterygoid plate, spongy bones, between the period of birth and the second year. Osseous union occurs first between the centres for the posterior body, and at about the same time between each centre of the anterior body and its corresponding (lesser) alæ; the third union takes place between the internal pterygoid plate and the greater alæ; the fourth between the two centres of the anterior body, and at the same time between the anterior and posterior body. This is the state of union at birth, the bone consisting of five centres, one being the body and lesser alæ; one on each side, the great alæ and internal pterygoid plate; and the remaining two the sphenoidal spongy bones. The greater alæ unite with the body during the first year; the spongy bones after puberty; and the body of the sphenoid with the basilar process of the occipital between eighteen and twenty-five.

Articulations.—With twelve bones; all the bones of the head and five of the face, viz. the two malar, two palate, and the vomer.

Attachment of Muscles.—To twelve pairs; temporal, external pterygoid, internal pterygoid, superior constrictor, tensor palati, laxator tympani, levator palpebræ, obliquus superior, superior rectus, internal rectus, inferior rectus, and external rectus.

Ethmoid Bone.—The ethmoid (ἀθμος, a sieve) is a square-shaped cellular bone, situated between the two orbits, at the root of the nose, and perforated upon its upper surface by a number of small openings, from which peculiarity it has received its name. It consists of a perpendicular lamella and two lateral masses.

The perpendicular lamella is a thin central plate, which articulates with the vomer and cartilage of the septum, and assists in forming the septum of the nose. It is surmounted superiorly by a thick and strong process, the crista galli, which projects into the cavity of the skull, and gives attachment to the falx cerebri. From the base of the anterior border of this process there project forwards two small plates, alar processes, which are received into corresponding depressions in the frontal bone, and often complete posteriorly the foramen cæcum. On each side of the crista galli, upon the upper surface of the bone, is a thin and grooved plate perforated by a number of small openings, the cribiform lamella, which supports the bulb of the olfactory nerve, and gives passage to its filaments, and to the nasal
branch of the ophthalmic nerve. In the groove of this lamella the foramina pierce the bone completely, but at either side they are the apertures of canals, which run for some distance in the substance of the central lamella, inner wall of the lateral mass and spongy bones. The opening for the nasal nerve is a narrow slit in the anterior part of the cribiform lamella, close to the crista galli. The cribiform lamella serves to connect the lateral masses with the perpendicular plate.

The lateral masses (labyrinths) are divisible into an internal and external surface, and four borders, superior, inferior, anterior, and posterior. The internal surface is rough and slightly convex, and forms the external boundary of the upper part of the nasal fossæ. Towards the posterior border of this surface is a narrow horizontal fissure, the superior meatus of the nose, the upper margin of which is thin, and somewhat curled inwards; hence it is named the superior turbinate bone (concha superior). Below the meatus is the convex surface of another thin plate, which is curled outwards, and forms the lower border of the mass, the middle turbinate bone (concha media). The external surface is quadrilateral and smooth, hence it is named os planum, and, from its thinness, lamina papyracea; it enters into the formation of the inner wall of the orbit.

The superior border is irregular and cellular, the cells being completed by the edges of the ethmoidal fissure of the frontal bone. This border is crossed by two grooves, sometimes complete canals, opening into the orbit by the anterior and posterior ethmoidal foramina. The inferior border is formed internally by the lower border of the middle turbinate bone, and externally by a concave irregular fossa, the upper boundary of the middle meatus. The anterior border presents a number of incomplete cells, which are closed by the superior maxillary

* The ethmoid bone seen from above and behind. 1. The central lamella. 2. 2. The lateral masses; the numbers are placed on the posterior border of the lateral mass at each side. 3. The crista galli process. 4. The cribiform plate of the left side, pierced by the cribiform foramina. 5. The hollow space immediately above and to the left of this number is the superior meatus. 6. The superior turbinate bone. 7. The middle turbinate bone; the numbers 5, 6, 7, are situated upon the internal surface of the left lateral mass, near its posterior part. The interval between these parts is the superior meatus. 8. The external surface of the lateral mass, or os planum. 9. The superior or frontal border of the lateral mass, grooved by the anterior and posterior ethmoidal canals. 10. Refers to the concavity of the middle turbinate bone, which is the upper boundary of the middle meatus.
and lachrymal bone; and the posterior border is irregularly cellular, to articulate with the sphenoid and palate bones.

The lateral masses are composed of cells, which are divided by a thin partition into anterior and posterior ethmoidal cells. The anterior, the most numerous, communicate with the frontal sinuses, and open by means of an irregular and incomplete tubular canal, the infundibulum, into the middle meatus. The posterior cells, fewer in number, open into the superior meatus.

Development. — By three centres; one for each lateral mass, and one for the perpendicular lamella. Ossification commences in the lateral masses at about the beginning of the fifth month, appearing first in the os planum and then in the spongy bones. During the latter half of the first year after birth, the central lamella and lamina cribrosa begin to ossify, and are united to the lateral masses by the beginning of the second. The cells of the ethmoid are developed in the course of the fourth and fifth year.

Articulations. — With thirteen bones; two of the cranium, — the frontal and sphenoid; the rest of the face, viz. the nasal, superior maxillary, lachrymal, palate, the inferior turbinate, and the vomer.

No muscles are attached to this bone.

**BONES OF THE FACE.**

The face is composed of fourteen bones; viz. the

- Two nasal,
- Two superior maxillary,
- Two lachrymal,
- Two malar,
- Two palatine,
- Two inferior turbinate,
- Vomer.
- Inferior maxillary.

**Nasal Bones.** — The nasal (fig. 28) are two small quadrangular bones, forming by their union the bridge and base of the nose. Upon the upper surface they are convex, and pierced by a foramen for a small artery; on the under surface they are somewhat concave, and marked by a groove, which lodges the nasal branch of the ophthalmic nerve. The superior border is narrow and thick, the inferior broad, thin, and irregular.

Development. — By a single centre for each bone, the first ossific deposition making its appearance at the same time as in the vertebral.

Articulations. — With four bones; frontal, ethmoidal, nasal, and superior maxillary.

Attachment of Muscles. — It has in relation with it the pyramidalis nasi, and compressor nasi; but neither of these muscles is inserted into it.

**Superior Maxillary Bones.** — The superior maxillary are the largest bones of the face, with the exception of the lower jaw; they form, by their union, the whole of the upper jaw, and assist in the construction of the nose, the orbit, the cheek, and the palate. Each bone is divisible into a body and four processes.
The body is triangular in form, and hollowed in its interior into a large cavity, the \textit{antrum maxillare} (antrum of Highmore). It presents for examination four surfaces, external or facial, internal or nasal, posterior or zygomatic, and superior or orbital.

The \textit{external}, or \textit{facial surface}, forms the anterior part of the bone; it is irregularly concave, and presents a deep depression towards its centre, the \textit{canine fossa}, which gives attachment to two muscles, the \textit{compressor nasi} and \textit{levator anguli oris}. Immediately above this fossa is the \textit{infra-orbital foramen}, the termination of the infra-orbital canal, transmitting the superior maxillary nerve, and infra-orbital artery; and above the infra-orbital foramen, the lower margin of the orbit, continuous externally with the rough articular surface of the malar process, and internally with a thick ascending plate, the nasal process. Towards the middle line of the face this surface is bounded by the concave border of the opening of the nose, which is projected forwards at its inferior termination into a sharp process, forming, with a similar process of the opposite bone, the \textit{nasal spine}. Beneath the nasal spine, and above the two superior incisor teeth, is a slight depression, the \textit{incisive}, or \textit{myrtiform fossa}, which gives origin to the depressor labii superioris alaeque nasi muscle. The myrtiform fossa is divided from the canine fossa by a perpendicular ridge, corresponding with the direction of the root of the canine tooth. The inferior boundary of the facial surface is the alveolar process which contains the teeth of the upper jaw; and it is separated from the zygomatic surface by a strong projecting eminence, the malar process.

The \textit{internal}, or \textit{nasal surface}, presents a large irregular opening, leading into the antrum maxillare; this opening is nearly closed in the

* The superior maxillary bone of the right side, as seen from the lateral aspect. 1. The external, or facial surface; the depression in which the figure is placed is the canine fossa. 2. The posterior, or zygomatic surface. 3. The superior, or orbital surface. 4. The infra-orbital foramen; it is situated immediately below the number. 5. The infra-orbital canal, leading to the infra-orbital foramen. 6. The inferior border of the orbit. 7. The malar process. 8. The nasal process. 9. The concavity forming the lateral boundary of the anterior nares. 10. The nasal spine. 11. The incisive, or myrtiform fossa. 12. The alveolar process. 13. The internal border of the orbital surface, which articulates with the ethmoid and palatine bone. 14. The concavity which articulates with the lachrymal bone, and forms the commencement of the nasal duct. 15 The crista nasalis of the palate process. i. The two incisor teeth. c. The canine. b. The two bicuspida. m. The three molares.
articulated skull by the ethmoid, palate, lachrymal, and inferior turbinated bones. The cavity of the antrum is somewhat triangular, corresponding in shape with the form of the body of the bone. Upon its inner wall are numerous grooves, lodging branches of the superior maxillary nerve, and projecting into its floor several conical processes, corresponding with the roots of the first and second molar teeth. In front of the opening of the antrum is the strong ascending plate of the nasal process, marked inferiorly by a rough horizontal ridge (crista turbinalis inferior), which gives attachment to the inferior turbinate bone. The concave depression immediately above this ridge corresponds with the middle meatus of the nose, and that below the ridge with the inferior meatus. Between the nasal process and the opening of the antrum, is a deep groove (sulcus lachrymalis) which is converted into a canal by the lachrymal and inferior turbinate bone, and constitutes the nasal duct. The superior border of the nasal surface is irregularly cellular, and articulates with the lachrymal and ethmoid bone; the posterior border is rough, and articulates with the palate bone; the anterior border is sharp, and forms the free margin of the opening of the nose; and from the inferior border projects inwards a strong horizontal plate, the palate process.

The posterior surface may be called zygomatic, from forming part of the zygomatic fossa; it is bounded externally by the malar process, and internally by a rough and rounded border, the tuberosity, which is pierced by a number of small foramina (foramina alveolaria posteriora), giving passage to the posterior dental nerves and branches of the superior dental artery. The lower part of this tuberosity presents a rough oval surface, to articulate with the palate bone, and immediately above and to the inner side of this articular surface a smooth groove, which forms part of the posterior palatine canal. The superior border is smooth and rounded to form the lower boundary of the sphenomaxillary fissure, and is marked by a notch, the commencement of the infra-orbital canal. The inferior boundary is the alveolar process, containing the two last molar teeth.

The orbital surface is triangular and thin, and constitutes the floor of the orbit. It is bounded internally by an irregular edge, which articulates with the palate, ethmoid, and lachrymal bone; posteriorly, by the smooth border which enters into the formation of the sphenomaxillary fissure; and, anteriorly, by a convex margin, partly smooth and partly rough, the smooth portion forming part of the lower margin of the orbit, and the rough articulating with the malar bone. The middle of this surface is channelled by a deep groove and canal, the infra-orbital, which terminates at the infra-orbital foramen; and near to the root of the nasal process is a slight depression, marking the origin of the inferior oblique muscle of the eyeball.

The four processes of the superior maxillary bone are the nasal, malar, alveolar, and palate.

The nasal process ascends by the side of the nose, to which it forms the lateral boundary, and articulates with the frontal and nasal bone.
By its external surface it gives attachment to the levator labii superioris alaeque nasi, and to the orbicularis palpebrarum muscle. Its internal surface contributes to form the inner wall of the nares, and is marked transversely by a horizontal ridge (crista turbinalis superior) which divides it into two portions, one above the ridge irregular and uneven, for giving attachment to and completing the cells of the lateral mass of the ethmoid; the other below, smooth and concave, corresponding with the middle meatus. The posterior border is thick and hollowed into a groove for the nasal duct. The margin of the nasal process, which is continuous with the lower border of the orbit, is sharp and marked by a small tubercle which serves as a guide to the introduction of the knife in the operation for fistula lachrymalis.

The malar process, large and irregular, is situated at the angle of separation between the facial and zygomatic surfaces, and presents a triangular surface for articulation with the malar bone.

The alveolar process forms the lower margin of the bone; it is spongy and cellular in texture, and excavated into deep holes for the reception of eight teeth.

The palate process is thick and strong, and projects horizontally inwards from the inner surface of the body of the bone. Superiorly, it is concave and smooth, and forms the floor of the nares; inferiorly, it is also concave but uneven, and assists in the formation of the roof of the palate. This surface is marked by a deep groove, which lodges the posterior palatine nerve and artery. Its internal edge is raised into a ridge (crista nasalis), which, with a corresponding ridge in the opposite bone, forms a groove for the reception of the vomer. The prolongation of this ridge forwards beyond the level of the facial surface of the bone is the nasal spine. At the anterior extremity of its nasal surface is a foramen, which leads into a canal formed conjointly by the two superior maxillary bones, the anterior palatine canal. The termination of this canal is situated immediately behind the incisor teeth, hence it is also named the incisive foramen. Associated with the incisive openings and canal are two smaller canals, the naso-palatine, which transmit the naso-palatine nerves. These canals are situated in the walls of the incisive canal, and terminate inferiorly in that canal, either by separate openings or conjoined.

Development.—By four centres; one for the anterior part of the palate, and incisive portion of the alveolar process (the permanence of this piece constitutes the intermaxillary bone of animals); one for that portion of the bone lying internally to the infra-orbital canal and foramen; one for that portion lying externally to the groove and canal; and one for the palate process. The superior maxillary bone is one of the earliest to shew signs of ossification, this process beginning in the alveolar process, and being associated with the early development of teeth. The early development of the alveolar process, and the consequent fusion at this point of the original pieces, explains the difficulties which have been felt by anatomists in determining the precise number of the ossifying centres.
Articulations.—With nine bones, viz.; with two of the cranium and with all the bones of the face excepting the inferior maxillary. These are, the frontal and ethmoid, nasal, lachrymal, malar, inferior turbinated, palate, vomer, and its fellow of the opposite side.

Attachment of muscles.—To nine; orbicularis palpebrarum, obliquus inferior oculi, levator labii superioris alaeque nasi, levator labii superioris proprius, levator anguli oris, compressor nasi, depressor labii superioris alaeque nasi, buccinator, masseter.

Lachrymal Bones—(os unguis, from an imagined resemblance to a finger nail). The lachrymal is a thin oval-shaped plate of bone, situated at the anterior and inner angle of the orbit. It may be divided into an external and internal surface and four borders. The external surface is smooth and marked by a vertical ridge, the lachrymal crest, into two portions, one of which is flat and enters into the formation of the orbit, hence may be called the orbital portion; the other is concave, and lodges the lachrymal sac, hence the lachrymal portion. The crest is expanded inferiorly into a hook-shaped process (hamulus lachrymalis) which forms part of the outer boundary of the fossa lachrymalis. The internal surface is uneven and completes the anterior ethmoid cells, it assists also in forming the wall of the nasal fossae and nasal duct. The four borders articulate with adjoining bones.

Development.—By a single centre appearing in the early part of the third month.

Articulations.—With four bones; two of the cranium, frontal and ethmoid; and two of the face, superior maxillary, and inferior turbinated bone.

Attachment of Muscles.—To one muscle, the tensor tarsi, and to an expansion of the tendo oculi, the former arising from the orbital surface, the other being attached to the lachrymal crest.

Malar Bones—(mala, the cheek). The malar (fig. 28) is the strong quadrangular bone which forms the prominence of the cheek. It is divisible into an external and internal surface and four processes, the frontal, orbital, maxillary, and zygomatic. The external surface is

* The lachrymal bone of the right side, viewed upon its external or orbital surface. 1. The orbital portion of the bone. 2. The lachrymal portion; the prominent ridge between these two portions is the crest. 3. The lower termination of the crest, the hamulus lachrymalis. 4. The superior border which articulates with the frontal bone. 5. The posterior border, which articulates with the ethmoid bone. 6. The anterior border which articulates with the superior maxillary bone. 7. The border which articulates with the inferior turbinated bone.
smooth and convex, and pierced by several small openings which give passage to filaments of the temporo-malar nerve and minute arteries. The *internal surface* is concave, partly smooth and partly rough; smooth where it forms part of the temporal fossa, and rough where it articulates with the superior maxillary bone.

The *frontal process* ascends perpendicularly to form the outer border of the orbit, and to articulate with the external angular process of the frontal bone. The *orbital process* is a thick plate, which projects inwards from the frontal process, and unites with the great ala of the sphenoid to constitute the outer wall of the orbit. It is pierced by several small foramina for the passage of temporo-malar filaments of the superior maxillary nerve. The *maxillary process* is broad, and articulates with the superior maxillary bone. The *zygomatic process*, narrower than the rest, projects backwards to unite with the zygoma of the temporal bone.

**Development.**—By a single centre; rarely by two or three. In many animals the malar bone is permanently divided into two portions, orbital and malar. Ossification commences in the malar bone soon after the vertebrae.

**Articulations.**—With *four* bones; three of the cranium, frontal, temporal, and sphenoid; and one of the face, the superior maxillary bone.

**Attachment of Muscles.**—To *five*; levator labii superioris proprius, zygomaticus minor and major, masseter, and temporal.

---

**Fig. 25.**

**Palate Bones.**—The palate bones are situated at the posterior part of the nares, where they enter into the formation of the palate, the side of the nose, and the posterior part of the floor of the orbit; hence they might with great propriety be named the palato-naso-orbital bones. Each bone resembles in general form the letter L, and is divisible into a horizontal plate, a perpendicular plate, and a pterygoid process or tuberosity.

The *horizontal plate* is quadrilateral; and presents two surfaces, one superior, which enters into the formation of the floor of the nares, the other inferior, forming the posterior part of the hard palate. The *superior surface*...
is concave and rises towards the middle line, where it unites with its fellow of the opposite side and forms part of a crest (crista nasalis), which articulates with the vomer. The inferior surface is uneven, and marked by a slight transverse ridge, to which is attached the tendinous expansion of the tensor palati muscle. Near to its external border are two openings, one large and one small, the posterior palatine foramina; the former transmits the posterior palatine nerve and artery, and the latter the middle palatine nerve. The posterior border is concave, and presents at its inner extremity a sharp point, which with a corresponding point in the opposite bone constitutes the palate spine for the attachment of the azygos uvulae muscle.

The perpendicular plate is also quadrilateral; and presents two surfaces, one internal or nasal, forming a part of the wall of the nares; the other external, bounding the sphenomaxillary fossa and antrum. The internal surface is marked near its middle by a horizontal ridge (crista turbinalis inferior), to which is united the inferior turbinate bone, and at about half an inch above this by another ridge (crista turbinalis superior) for the attachment of the middle turbinate bone. The concave surface below the inferior ridge is the lateral boundary of the inferior meatus of the nose; that between the two ridges corresponds with the middle meatus, and the surface above the superior ridge with the superior meatus. The external surface, extremely irregular, is rough on each side for articulation with neighbouring bones, and smooth in the middle to constitute the inner boundary of the sphenomaxillary fossa. This smooth surface terminates inferiorly in a deep groove, which being completed by the tuberosity of the superior maxillary bone and pterygoid process of the sphenoid, forms the posterior palatine canal.

Near the upper part of the perpendicular plate is a large oval notch completed by the sphenoid, the sphenopalatine foramen, which transmits the sphenopalatine nerves and artery, and serves to divide the upper extremity of the bone into two portions, an anterior or orbital, and a posterior or sphenoidal portion. The orbital portion is hollow within, and presents five surfaces externally; three articular, and two free; the three articular are the anterior, which looks forward and articulates with the superior maxillary bone, internal with the ethmoid, and posterior with the sphenoid. The free surfaces are the superior or orbital, which forms the posterior part of the floor of the orbit, and forms the crista nasalis for the reception of the vomer. 5. The pointed process, which with a similar process of the opposite bone forms the palate spine. 6. The horizontal ridge which gives attachment to the inferior turbinate bone; the concavity below this ridge enters into the formation of the inferior meatus, and the concavity (2) above the ridge into that of the middle meatus. 7. The sphenopalatine notch. 8. The orbital portion. 9. The crista turbinalis superior for the middle turbinate bone. 10. The middle facet of the tuberosity, which enters into the formation of the pterygoid fossa. The facets 11 and 3 articulate with the two pterygoid plates, 11 with the internal, and 3 with the external.
the external, which looks into the sphen-maxillary fossa.

The sphenoidal portion, much smaller than the orbital, has three surfaces, two lateral and one superior. The external lateral surface enters into the formation of the sphen-maxillary fossa; the internal lateral forms part of the lateral boundary of the nares; and the superior surface articulates with the under part of the body of the sphenoid bone, and assists the sphenoidal spongy bones in closing the sphenoidal sinuses. This portion takes part in the formation of the pterygo-palatine canal.

The pterygoid process or tuberosity of the palate bone is the thick and rough process which stands backwards from the angle of union of the horizontal with the perpendicular portion of the bone. It is received into the angular fissure, which exists between the two plates of the pterygoid process at their inferior extremity, and presents three surfaces: one concave and smooth, which forms part of the pterygoid fossa; and one at each side to articulate with the pterygoid plates. The anterior face of this process is rough and articulates with the superior maxillary bone.

Development.—By a single centre, which appears in the angle of union between the horizontal and perpendicular portion, at the same time with ossification in the vertebrae.

Articulations.—With six bones; two of the cranium, the sphenoid and ethmoid; and four of the face, the superior maxillary, inferior turbinated bone, vomer, and the palate bone of the opposite side.

Attachment of Muscles.—To four; the tensor palati, azygos uvula, internal and external pterygoid.

Inferior Turbinated Bones.—The inferior turbinated or spongy bone, is a thin layer of light and porous bone, attached to the crista turbinalis inferior of the inner wall of the nares, and projecting inwards towards the septum narium. The inferior turbinated bone is broad in front, narrow and tapering behind, and slightly curled upon itself, so as to bear some resemblance to one valve of a bivalve shell.
hence its designation *concha inferior*. The bone presents for examination a convex and concave surface, and a superior and inferior border. The *convex surface* looks inwards and upward, and forms the inferior boundary of the middle meatus naris; it is marked by several longitudinal grooves for branches of the sphenopalatine nerve and artery. The *concave surface* looks downwards and outwards, and constitutes the roof of the inferior meatus. The *superior border* is irregular; it is attached to the crista turbinalis inferior of the superior maxillary bone in front, to the same crest on the palate bone behind, and between those attachments gives off two, and sometimes three, thin and laminated processes. The most anterior of these processes, *processus lachrymalis*, articulates with the lachrymal bone, and assists in completing the nasal duct. The middle process, *processus maxillaris*, descends and assists in closing the antrum maxillare; while the posterior, *processus ethmoidalis*, which is often wanting, ascends towards the ethmoid bone, and also takes part in the closure of the antrum maxillare. The *inferior border* is rounded, and thicker than the rest of the bone.

**Development.**—By a single centre which appears at about the middle of the first year.

It affords no attachment to muscles.

**Articulations.**—With four bones; the ethmoid, superior maxillary, lachrymal, and palate.

**Vomer.**—The vomer is a thin quadrilateral plate of bone, forming the posterior and inferior part of the septum of the nares.

The *superior border* is broad and expanded to articulate, in the middle with the under surface of the body of the sphenoid, and on each side with the processus vaginalis of the pterygoid process. The anterior part of this border is hollowed into a sheath for the reception of the rostrum of the sphenoid. The *inferior border* is thin and irregular, and is received into the grooved summit of the crista nasalis. The *posterior border* is sharp and free and forms the posterior division of the two nares. The *anterior border* is more or less deeply grooved for the reception of the central lamella of the ethmoid and cartilage of the septum. This groove is an indication of the early constitution of the bone of two lamellae, united at the inferior border. The vomer not unfrequently presents a convexity to one or the other side, generally it is said, to the left.

**Development.**—By a single centre, which makes its appearance at the same time with those of the vertebrae. Ossification begins from below and proceeds upwards. At birth the vomer presents the form of a trough in the concavity of which the cartilage of the septum nasi is placed; it is this disposition which subsequently enables the bone to embrace the rostrum of the sphenoid.

The vomer has no muscles attached to it.

**Articulations.**—With six bones; the sphenoid, ethmoid, two superior maxillary, and two palate bones, and with the cartilage of the septum.
INFERIOR MAXILLARY BONE.—The lower jaw is the arch of bone which contains the inferior teeth; it is divisible into a horizontal portion or body, and a perpendicular portion, the ramus, at each side.

Upon the external surface of the body of the bone, at the middle line, and extending from between the two first incisor teeth to the chin, is a slight ridge, crista mentalis, which indicates the point of conjunction of the lateral halves of the bone in the young subject, the symphysis. Immediately external to this ridge is a depression which gives origin to the depressor labii inferioris muscle; and corresponding with the root of the lateral incisor tooth, another depression, the incisive fossa, for the levator labii inferioris. Further outwards is an oblique opening, the mental foramen, for the exit of the inferior dental nerve and artery, and below this foramen, the commencement of an oblique ridge which runs upwards and outwards to the base of the coronoid process and gives attachment to the depressor anguli oris, platysma myoides, and buccinator muscles. Near to the posterior part of this surface is a rough impression made by the masseter muscle; and immediately in front of this impression, a groove may occasionally be seen for the facial artery. The projecting tuberosity at the posterior extremity of the lower jaw, at the point where the body and ramus meet, is the angle.

Upon the internal surface of the body of the bone at the symphysis, are two small pointed tubercles; immediately beneath these, two other tubercles less marked and pointed, beneath them a ridge, and beneath the ridge two rough depressions of some size. These four points give attachment from above downwards to the genio-hyo-glossi, genio-hyoides, part of the mylo-hyoides and to the digastric muscles. Running outwards into the body of the bone from the above ridge is a prominent line, the mylo-hyoides ridge, which gives attachment to the mylo-hyoides muscle, and by its extremity to the pterygo-maxillary ligament and superior constrictor muscle. Immediately above the ridge, and by the side of the symphysis, is a smooth concave surface, which corresponds with the sublingual gland; and below the ridge, and more externally, a deeper fossa for the submaxillary gland.

The superior border of the body of the bone is the alveolar process, furnished in the adult with alveoli for sixteen teeth. The inferior border or base is rounded and smooth; thick and everted in front to form the chin, and thin behind where it merges in the angle of the bone.

The ramus is a strong square-shaped process, differing in direction at various periods of life; thus, in the foetus and infant, it is almost parallel with the body; in youth it is oblique, and gradually increases in the vertical direction until manhood; in old age, after the loss of the teeth, it again declines and assumes the oblique direction. Upon its external surface it is rough, for the attachment of of the masseter muscle; and at the junction of its posterior border with the body of the bone, is a rough tuberosity, the angle of the
lower jaw, which gives attachment by its inner margin to the stylo-
maxillary ligament.

The upper extremity of the ramus presents two processes, separated
by a concave sweep, the sigmoid notch. The anterior is the coronoid
process; it is sharp and pointed, and gives attachment by its inner surface
to the temporal muscle. The anterior border of the coro-
noid process is grooved at its lower part for the buccinators muscle. The poste-
rior process is the condyle of the lower jaw, which is flattened from before back-
wards, oblique in direction, and smooth upon its upper surface, to articulate with
the glenoid cavity of the temporal bone. The con-
striction around the base of
the condyle is its neck, into which is inserted the external pterygoid
muscle. The sigmoid notch is crossed by the masseteric artery and
nerve.

The internal surface of the ramus is marked near its centre by a
large oblique foramen, the inferior dental, for the entrance of the inferior dental artery and nerve into the dental canal. Bounding this opening is a sharp margin, to which is attached the internal lateral ligament, and passing downwards from the opening a narrow groove which lodges the mylo-hyoidean nerve with a small artery and vein. To the uneven surface above, and in front of the inferior dental fora-
men, is attached the temporal muscle, and to that below it the internal pterygoid. The internal surface of the neck of the condyle gives at-
tachment to the external pterygoid muscle; and the angle to the stylo-
maxillary ligament.

Development.—By two centres; one for each lateral half, the two
sides meeting at the symphysis, where they become united. The lower jaw is the earliest of the bones of the skeleton to exhibit ossifi-
cation, with the exception of the clavicle; ossific union of the sym-
physis takes place during the first year.

Sutures.

The bones of the cranium and face are connected with each other by means of sutures (sutura, a seam), of which there are four principal varieties,—serrated, squamous, harmonia, and schindylesis.

The serrated suture is formed by the union of two borders possessing serrated edges, as in the coronal, sagittal, and lambdoid sutures. In these sutures the serrations are formed almost wholly by the external table, the edges of the internal table lying merely in apposition.

The squamous suture (squama, a scale) is formed by the overlapping of the bevelled edges of two contiguous bones, as in the articulation between the temporal and lower border of the parietal. In this suture the approximated surfaces are roughened, so as to adhere mechanically with each other.

The harmonia suture (ἀκαθάριστος, to adapt) is the simple apposition of contiguous surfaces, the surfaces being more or less rough and retentive. This suture is seen in the connection between the superior maxillary bones, or of the palate processes of the palate bones with each other.
The *schindylesis suture* (*σχινδυλησις*, a fissure) is the reception of one bone into a sheath or fissure of another, as occurs in the articulation of the rostrum of the sphenoid with the vomer, or of the latter with the perpendicular lamella of the ethmoid, and with the crista nasalis of the superior maxillary and palate bones.

The serrated suture is formed by the interlocking of the radiating fibres along the edges of the flat bones of the cranium during growth. When this process is retarded in the infant by over distention of the head, as in hydrocephalus, and sometimes without any such apparent cause, distinct ossific centres are developed in the interval between the edges; and, being surrounded by the suture, form independent pieces, which are called *ossa triquetra*, or *ossa Wormiana*. In the lambdoidal suture there is generally one or more of these bones; and, in a beautiful adult hydrocephalic skeleton in the possession of Mr. Liston, there are upwards of one hundred.

The *coronal suture* (fig. 28) extends transversely across the vertex of the skull, from the upper part of the greater wing of the sphenoid to the same point on the opposite side; it connects the frontal with the parietal bones. In the formation of this suture the edges of the articulating bones are bevelled, so that the parietal rest upon the frontal at each side, and in the middle the frontal rests upon the parietal bones; they thus afford each other mutual support in the consolidation of the skull.

The *sagittal suture* (fig. 28) extends longitudinally backwards along the vertex of the skull, from the middle of the coronal to the apex of the lambdoidal suture. It is very much serrated, and serves to unite the two parietal bones. In the young subject, and sometimes in the adult, this suture is continued through the middle of the frontal bone to the root of the nose, under the name of the frontal suture. Ossa triquetra are sometimes found in the sagittal suture.

The *lambdoidal suture* is named from some resemblance to the Greek letter Λ, consisting of two branches, which diverge at an acute angle from the extremity of the sagittal suture. This suture connects the occipital with the parietal bones. At the posterior and inferior angle of the parietal bones, the lambdoidal suture is continued onwards in a curved direction into the base of the skull, and serves to unite the occipital bone with the mastoid portion of the temporal, under the name of the *additamentum suture* *lambdoidalis*. It is in the lambdoidal suture that *ossa triquetra* occur most frequently.

The *squamous suture* (fig. 28) unites the squamous portion of the temporal bone with the greater ala of the sphenoid and with the parietal, overlapping the lower border of the latter. The portion of the suture which is continued backwards from the squamous portion of the bone to the lambdoidal suture, and connects the mastoid portion with the posterior inferior angle of the parietal, is the *additamentum suture* *squamose*.

The *additamentum suture* *lambdoidalis* and *additamentum suture* *squamose*, constitute together the *mastoid suture*. 
Across the upper part of the face is an irregular suture, the transverse, which connects the frontal bone with the nasal, superior maxillary, lachrymal, ethmoid, sphenoid, and malar bones. The other sutures are too unimportant to deserve particular names or description.

**REGIONS OF THE SKULL.**

The skull, considered as a whole, is divisible into four regions,—a superior region, or vertex; a lateral region; an inferior region, or base; and an anterior region, the face.

*Fig. 28.*

The **SUPERIOR REGION,** or vertex of the skull, is bounded anteriorly by the frontal eminences; on each side by the temporal ridges and parietal eminences; and behind by the superior curved line of the

* A front view of the skull. 1. The frontal portion of the frontal bone. The 2, immediately over the root of the nose, refers to the nasal tuberosity; the 3, over the orbit, to the supra-orbital ridge. 4. The optic foramen. 5. The sphenoidal fissure. 6. The spheno-maxillary fissure. 7. The lachrymal fossa in the lachrymal bone, the commencement of the nasal duct. The figures 4, 5, 6, 7, are within the orbit. 8. The opening of the anterior nares, divided into two parts by the vomer; the number is placed upon the latter. 9. The infra-orbital foramen. 10. The malar bone. 11. The symphysis of the lower jaw. 12. The mental foramen. 13. The ramus of the lower jaw. 14. The parietal bone. 15. The coronal suture. 16. The temporal bone. 17. The squamous suture. 18. The upper part of the great ala of the sphenoid bone. 19. The commencement of the temporal ridge. 20. The zygoma of the temporal bone, assisting to form the zygomatic arch. 21. The mastoid process.
occipital bone and occipital protuberance. It is crossed transversely by the coronal suture, and marked from before backwards by the sagittal, which terminates posteriorly in the lambdoid suture. Near

the posterior extremity of the region, and on each side of the sagittal suture, is the parietal foramen.

Upon the inner, or cerebral surface of this region is a shallow groove, extending along the middle line from before backwards, for the superior longitudinal sinus; on either side of this groove are

The anterior clinoid process. 9. The carotid groove upon the side of the sella turcica, for the internal carotid artery and cavernous sinus. 10, 11, 12. The middle fossa of the base of the skull. 10. Marks the great ala of the sphenoid. 11. The squamous portion of the temporal bone. 12. The petrous portion of the temporal. 13. The sella turcica. 14. The basilar portion of the sphenoid and occipital bone (clivus Blumenbachii). The uneven ridge between Nos. 13, 14, is the dorsum ephiippii, and the prominent angles of this process the posterior clinoid processes. 15 The foramen rotundum. 16. The foramen ovale. 17. The foramen spinosum; the small irregular opening between 17 and 12 is the hiatus Fallopii. 18. The posterior fossa of the base of the skull. 19, 19. The groove for the lateral sinus. 20. The ridge upon the occipital bone, which gives attachment to the falx cerebelli. 21. The foramen magnum. 22. The meatus auditorius internus. 23. The jugular foramen.
several small fossae for the Pacchionian bodies, and further outwards digital fossae corresponding with the convexities of the convolutions and numerous ramified markings for lodging the branches of the artery meningea media.

The *lateral region* of the skull is divisible into three portions; temporal, mastoid, and zygomatic.

The *temporal portion*, or *temporal fossa*, is bounded above and behind by the temporal ridge, in front by the external angular process of the frontal bone and by the malar bone, and below by the zygoma. It is formed by part of the frontal, great wing of the sphenoid, parietal, squamous portion of the temporal, malar bone and zygoma, and lodges the temporal muscle with the deep temporal arteries and nerves.

The *mastoid portion* is rough, for the attachment of muscles. Upon its posterior part is the mastoid foramen, and below, the mastoid process. In front of the mastoid process is the external auditory foramen, surrounded by the external auditory process; and in front of this foramen the glenoid cavity, bounded above by the middle root of the zygoma and in front by its tubercle.

The *zygomatic portion*, or *fossa*, is the irregular cavity below the zygoma, bounded in front by the superior maxillary bone, internally by the external pterygoid plate, above by part of the great wing of the sphenoid and squamous portion of the temporal bone, and by the temporal fossa, and externally by the zygomatic arch and ramus of the lower jaw. It contains the external pterygoid, with part of the temporal and internal pterygoid muscle, and the internal maxillary artery and inferior maxillary nerve, with their branches. At the bottom of the zygomatic fossa are two fissures, the spheno-maxillary and the pterygo-maxillary. The *spheno-maxillary fissure* is horizontal in direction, opens into the orbit, and is situated between the great ala of the sphenoid and the superior maxillary bone. It is completed externally by the malar bone. The *pterygo-maxillary fissure* is vertical, and descends at right angles from the extremity of the preceding. It is situated between the pterygoid process and the tuberosity of the superior maxillary bone, and transmits the internal maxillary artery. At the angle of junction of these two fissures is a small cavity, the *spheno-maxillary fossa*, bounded by the sphenoid, palate, and superior maxillary bones, in which are seen the openings of five foramina,—the foramen rotundum, spheno-palatine, pterygo-palatine, posterior palatine, and Vidian. It lodges Meckel's ganglion and the termination of the internal maxillary artery.

The *base of the skull* presents an internal or cerebral, and an external or basilar surface.

The *cerebral surface* is divisible into three parts, which are named the anterior, middle, and posterior fossa of the base of the cranium. The *anterior fossa* is somewhat convex on each side, where it corresponds with the roofs of the orbits; and concave in the middle, in the situation of the ethmoid bone and the anterior part of the body of the sphenoid. The latter and the lesser wings constitute its posterior
boundary. It supports the anterior lobes of the cerebrum. In the middle line of this fossa, at its anterior part, is the crista galli, immediately in front of this process, the foramen caecum, and on each side the cribriform plate, with its foramina, for the transmission of the filaments of the olfactory and nasal branch of the ophthalmic nerve. Farther back in the middle line is the processus olivaris, and on the sides of this process the optic foramina, anterior and middle clinoid processes, and vertical grooves for the internal carotid arteries.

The middle fossa of the base, deeper than the preceding, is bounded in front by the lesser wing of the sphenoid; behind, by the petrous portion of the temporal bone; and is divided into two lateral parts by the sella turcica. It is formed by the posterior part of the body, great ala, and spinous process of the sphenoid, and by the petrous and squamous portion of the temporal bones. In the centre of this fossa is the sella turcica which lodges the pituitary gland, bounded in front by the anterior and middle and behind by the posterior clinoid processes. On each side of the sella turcica is the carotid groove for the internal carotid artery, the cavernous plexus of nerves, the cavernous sinus, and the orbital nerves, and a little farther outwards the following foramina from before backwards, sphenoidal fissure (foramen lacerum anterius) for the transmission of the third, fourth, three branches of the ophthalmic division of the fifth, and the sixth nerve, and ophthalmic vein; foramen rotundum, for the superior maxillary nerve; foramen ovale, for the inferior maxillary nerve, arteria meningea parva, and nervus petrosus superficialis minor; foramen spinosum, for the arteria meningea media; foramen lacerum basis cranii, which gives passage to the internal carotid artery, carotid plexus, and petrosal branch of the Vidian nerve. On the anterior surface of the petrous portion of the temporal bone is a groove, leading to a fissured opening, the hiatus Fallopii, for the petrosal branch of the Vidian nerve; and immediately beneath this a smaller foramen, for the nervus petrosus superficialis minor. Towards the apex of this portion of bone is the notch for the fifth nerve, and below it a slight depression for the Casserian ganglion. Farther outwards is the eminence which marks the position of the perpendicular semi-circular canal. Proceeding from the foramen spinosum are two grooves which indicate the course of the trunks of the arteria meningea media. The whole fossa lodges the middle lobes of the cerebrum.

The posterior fossa, larger than the other two, is formed by the occipital bone, by the petrous and mastoid portion of the temporals, and by a small part of the sphenoid and parietales. It is bounded in front by the upper border of the petrous portion and dorsum ephippii, and along its posterior circumference by the groove for the lateral sinuses; it gives support to the pons Varolii, medulla oblongata and cerebellum. In the centre of this fossa is the foramen magnum bounded on each side by a rough tubercle, which gives attachment to the odontoid ligament, and by the anterior condyloid foramen. In front of the foramen magnum is the concave surface (clivus Blumenbachii)
which supports the medulla oblongata and pons Varolii, and on each side the following foramina from before backwards. The internal auditory foramen, for the auditory and facial nerve and auditory artery; behind, and external to this is a small foramen leading into the aqueductus vestibuli; and below it, partly concealed by the edge of the petrous bone, the aqueductus cochleæ; next, a long fissure, the foramen lacerum posterius, or jugular foramen, giving passage ex-

The incisive, or anterior palatine foramen. 3. The palate process of the palate bone. The large opening near the figure is the posterior palatine foramen. 4. The palate spine; the curved line upon which the number rests, is the transverse ridge. 5. The vomer, dividing the openings of the posterior nares. 6. The internal pterygoid plate. 7. The scaphoid fossa. 8. The external pterygoid plate. The interval between 6 and 8 (right side of the figure), is the pterygoid fossa. 9. The zygomatic fossa. 10. The basilar process of the occipital bone. 11. The foramen magnum. 12. The foramen ovale. 13. The foramen spinosum. 14. The glenoid fossa. 15. The meatus auditorius externus. 16. The foramen lacerum anterius basis cranii. 17. The carotid foramen of the left side. 18. The foramen lacerum posterius, or jugular foramen. 19. The styloid process. 20. The stylo-mastoid foramen. 21. The mastoid process. 22. One of the condyles of the occipital bone. 23. The posterior condyloid fossa.
ternally to the commencement of the internal jugular vein and internally to the eighth pair of nerves. Converging towards this foramen from behind is the deep groove for the lateral sinus, and from the front the groove for the inferior petrosal sinus.

Behind the foramen magnum is a longitudinal ridge, which gives attachment to the falx cerebelli, and divides the two inferior fossae of the occipital bone; and above the ridge is the internal occipital protuberance and the transverse groove lodging the lateral sinus.

The external surface of the base of the skull is extremely irregular. From before backwards it is formed by the palate processes of the superior maxillary and palate bones; the vomer; pterygoid, spinous processes, and part of the body of the sphenoid; under surface of the squamous, petrous, and mastoid portion of the temporals; and by the occipital bone. The palate processes of the superior maxillary and palate bones constitute the hard palate, which is raised above the level of the rest of the base, and is surrounded by the alveolar processes containing the teeth of the upper jaw. At the anterior extremity of the hard palate, and directly behind the front incisor teeth, is the anterior palatine or incisive foramen, the termination of the anterior palatine canal, which contains the naso-palatine ganglion, and transmits the anterior palatine nerves. At the posterior angles of the palate are the posterior palatine foramina, for the posterior palatine nerves and arteries. Passing inwards from these foramina are the transverse ridges to which are attached the expansions of the tensor palati muscles, and at the middle line of the posterior border the palate spine which gives origin to the azygos uvulae. The hard palate is marked by a crucial suture, which distinguishes the four processes of which it is composed. Behind, and above the hard palate, are the posterior nares, separated by the vomer, and bounded on each side by the pterygoid processes. At the base of the pterygoid processes are the pterygo-palatine canals. The internal pterygoid plate is long and narrow, terminated at its apex by the hamular process, and at its base by the scaphoid fossa. The external plate is broad; the space between the two is the pterygoid fossa; it contains part of the internal pterygoid muscle, and the tensor palati. Externally to the external pterygoid plate is the zygomatic fossa. Behind the nasal fossa, in the middle line, is the under surface of the body of the sphenoid, and the basilar process of the occipital bone, and, still further back, the foramen magnum. At the base of the external pterygoid plate, on each side, is the foramen ovale, and behind this the foramen spinosum with the prominent spine which gives attachment to the internal lateral ligament of the lower jaw and the laxator tympani muscle. Running outwards from the apex of the spinous process of the sphenoid bone, is the fissura Glaseri, which crosses the glenoid fossa transversely, and divides it into an anterior smooth surface, bounded by the eminentia articularis, for the condyle of the lower jaw, and a posterior rough surface for a part of the parotid gland. Behind the foramen ovale and spinosum, is the irregular fissure between the
spinous process of the sphenoid bone and the petrous portion of the temporal, the foramen lacerum anterius basis cranii, which lodges the internal carotid artery and Eustachian tube, and in which the carotid branch of the Vidian nerve joins the carotid plexus. Following the direction of this fissure outwards is the foramen for the Eustachian tube, and that for the tensor tympani muscle, separated from each other by the processus cochleariformis. Behind the fissure is the pointed process of the petrous bone which gives origin to the levator palati muscle, and, externally to this process, the carotid foramen for the transmission of the internal carotid artery and the ascending branch of the superior cervical ganglion of the sympathetic; and behind the carotid foramen, the foramen lacerum posterius and jugular fossa. Externally, and somewhat in front of the latter, is the styloid process, and at its base the vaginal process. Behind and at the root of the styloid process is the stylo-mastoid foramen, for the facial nerve and stylo-mastoid artery, and further outwards the mastoid process. Upon the inner side of the root of the mastoid process is the digastric fossa; and a little farther internally, the occipital groove. On either side of the foramen magnum, and near its anterior circumference, are the condyles of the occipital bone. In front of each condyle, and piercing its base, is the anterior condyloid foramen for the hypoglossal nerve, and directly behind the condyle the irregular fossa in which the posterior condyloid foramen is situated. Behind the foramen magnum are the two curved lines of the occipital bone, the spine, and protuberance, with the rough surfaces for the attachment of muscles.

The Face is somewhat oval in contour, uneven in surface, and excavated for the reception of two principal organs of sense,—the eye and the nose. It is formed by part of the frontal bone and by the bones of the face. Superiorly it is bounded by the frontal eminences; beneath these are the superciliary ridges, converging towards the nasal tuberosity; beneath the superciliary ridges are the supra-orbital ridges, terminating externally in the external border of the orbit, and internally in the internal border, and presenting towards their inner third the supra-orbital notch, for the supra-orbital nerve and artery. Beneath the supra-orbital ridges are the openings of the orbits. Between the orbits is the bridge of the nose, overarchiing the anterior nares; and on each side of this opening the canine fossa of the superior maxillary bone, the infra-orbital foramen, and still farther outwards the prominence of the malar bone; at the lower margin of the anterior nares is the nasal spine, and beneath this the superior alveolar arch containing the teeth of the upper jaw. Forming the lower boundary of the face is the lower jaw, containing in its alveolar process the lower teeth, and projecting inferiorly to form the chin; on either side of the chin is the mental foramen. If a perpendicular line be drawn from the inner third of the supra-orbital ridge to the inner third of the body of the lower jaw, it will be found to intersect three openings;—the supra-orbital, infra-orbital, and mental, each giving passage to a facial branch of the fifth nerve.
ORBITS.

The orbits are two quadrilateral hollow cones, situated in the upper part of the face, and intended for the reception of the eye-balls, with their muscles, vessels, and nerves, and the lachrymal glands. The central axis of each orbit is directed outwards, so that the axes of the two continued into the skull through the optic foramina, would intersect over the middle of the sella turcica. The superior boundary of the orbit is formed by the orbital plate of the frontal bone, and by part of the lesser wing of the sphenoid; the inferior, by part of the malar bone and by the orbital processes of the superior maxillary and palate bone; the internal by the lachrymal bone, the os planum of the ethmoid and part of the body of the sphenoid; and the external, by the orbital process of the malar bone and the great ala of the sphenoid; these may be expressed more clearly in a tabular form:—

<table>

</tbody>
</table>

There are nine openings communicating with the orbit:—the optic, for the admission of the optic nerve and ophthalmic artery; the sphenoidal fissure, for the transmission of the third, fourth, the three branches of the ophthalmic division of the fifth and the sixth nerve, and the ophthalmic vein; the spheno-maxillary fissure, for the passage of the superior maxillary nerve and artery to the opening of entrance of the infra-orbital canal; temporo-malar foramina—two or three small openings in the orbital process of the malar bone, for the passage of filaments of the orbital branch of the superior maxillary nerve; anterior and posterior ethmoidal foramina in the suture between the os planum and frontal bone, the former transmitting the nasal nerve and anterior ethmoidal artery, and the latter the posterior ethmoidal artery and vein; the opening of the nasal duct; and the supra-orbital notch or foramen, for the supra-orbital nerve and artery.

NASAL FOSSÆ.

The nasal fossæ are two irregular cavities, situate in the middle of the face, and extending from before backwards. They are bounded above by the nasal bones, ethmoid, and sphenoid; below by the palate processes of the superior maxillary and palate bones; externally by the
superior maxillary, lachrymal, inferior turbinated, ethmoid, palate, and internal pterygoid plate of the sphenoid; and the two fossae are separated by the vomer and the perpendicular lamella of the ethmoid. These may be more clearly expressed in a tabular form:

<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>

</thead>
<tbody>
<tr>
<td>Palate processes of superior maxillary.</td>
<td>Palate processes of palate bone.</td>
<td></td>
</tr>
</tbody>
</table>

Each nasal fossa is divided into three irregular longitudinal passages, or meatuses, by three processes of bone, which project from its outer wall, the superior, middle, and inferior turbinated bones; the supe-

* A longitudinal section of the nasal fossae made immediately to the right of the middle line, and the bony septum removed in order to show the external wall of the left fossa. 1. The frontal bone. 2. The nasal bone. 3. The crista
rior and middle turbinated bones being processes of the ethmoid, and the inferior a distinct bone of the face. The superior meatus occupies the superior and posterior part of each fossa; it is situated between the superior and middle turbinated bones, and has opening into it three foramina, viz., the opening of the posterior ethmoid cells, the opening of the sphenoid cells, and the spheno-palatine foramen. The middle meatus is the space between the middle and inferior turbinated bones; it also presents three foramina, the opening of the frontal sinuses, of the anterior ethmoid cells, and of the antrum. The largest of the three passages is the inferior meatus, which is the space between the inferior turbinated bone and the floor of the fossa; in it there are two foramina, the termination of the nasal duct, and one opening of the anterior palatine canal. The nasal fossae commence upon the face by a large irregular opening, the anterior nares, and terminate posteriorly in the two posterior nares.

TEETH.

Man is provided with two successions of teeth; the first are the teeth of childhood, they are called temporary, deciduous, or milk teeth; the second continue until old age, and are named permanent.

The permanent teeth are thirty-two in number, sixteen in each jaw; they are divisible into four classes,—incisors, of which there are four in each jaw, two central and two lateral; canine, two above and two below; bicuspids, four above and four below; and molars, six above and six below.

The temporary teeth are twenty in number; eight incisors, four ca-
galli process of the ethmoid. The groove between 1 and 3 is the lateral bound-
ary of the foramen caecum. 4. The cribiform plate of the ethmoid. 5. Part of the sphenoidal bone. 6. The basilar portion of the sphenoid bone. Bones 2, 4, and 5, form the superior boundary of the nasal fossa. 7, 7. The articula-
ting surface of the palatine process of the superior maxillary bone. The groove between 7, 7, is the lateral half of the incisive canal, and the dark aper-
ture in the groove the inferior termination of the left naso-palatine canal.
8. The nasal spine. 9. The palatine process of the palatine bone. a. The superi-
or turbinated bone, marked by grooves and apertures for filaments of the olfactory nerve. b. The superior meatus. c. A probe passed into the posterior ethmoidal cells. d. The opening of the sphenoidal cells into the superior meatus. e. The sphenopalatine foramen. f. The middle turbinated bone. g, g. The middle meatus. h. A probe passed into the infundibular canal, leading from the frontal sinuses and anterior ethmoid cells; the triangular aperta-
ture immediately above the letter is the opening of the maxillary sinus.

The anterior letters g, k, are placed on the superior maxillary bone, the posterior on the palate bone. m. The internal pterygoid plate. n. Its hamular process. o. The external pterygoid plate. p. The situation of the opening of the Eustachian tube. q. The posterior palatine foramina, the letter is placed on the hard palate. r. The roof of the left orbit. s. The optic foramen. t. The groove for the last turn of the internal carotid artery converted into a foramen by the development of an osseous communication between the anterior and middle clinoid processes. v. The sella turcica. z. The posterior clinoid process.
nine, and eight molars. The temporary molars have four tubercles, and are succeeded by the permanent bicuspides, which have only two tubercles.

Each tooth is divisible into a crown, which is the part apparent above the gum; a constricted portion around the base of the crown, the neck; and a root or fang, which is contained within the alveolus. The root is invested by periosteeum, which lines the alveolus, and is then reflected upon the root of the tooth as far as its neck.

The incisor teeth (cutting teeth) are named from presenting a sharp and cutting edge, formed at the expense of the posterior surface. The crown is flattened from before backwards, being somewhat convex in front and concave behind; the neck is considerably constricted, and the root compressed from side to side; at its apex is a small opening for the passage of the nerve and artery of the tooth.

The canine teeth (cuspidati) follow the incisors in order from before backwards; two are situated in the upper jaw, one on each side, and two in the lower. The crown is larger than that of the incisors, convex before and concave behind, and tapering to a blunted point. The root is longer than that of all the other teeth, compressed at each side, and marked by a slight groove.

The bicuspid teeth (bicuspidati, small molars), two on each side in each jaw, follow the canine, and are intermediate in size between them and the molars. The crown is compressed from before backwards, and surmounted by two tubercles, one internal, the other external; the neck is oval; the root compressed, marked on each side by a deep groove, and bifid near its apex. The teeth of the upper jaw have a greater tendency to the division of their roots than those of the lower, and the posterior than the anterior pair.

The molar teeth (multicuspidati, grinders), three on each side in each jaw, are the largest of the permanent set. The crown is quadrilateral, and surmounted by four tubercles, the neck large and round, and the root divided into several fangs. In the upper jaw the first and second molar teeth have three roots, sometimes four, which are more or less widely separated from each other, two of the roots being external, the other internal. In the lower there are but two roots, which are anterior and posterior; they are flattened from behind forwards, and grooved so as to mark a tendency to division. The third molars, or dentes sapientiae, are smaller than the other two; they present three tubercles on the surface of the crown; and the root is single and grooved, appearing to be made up of four or five fangs compressed together, or partially divided. In the lower jaw the fangs are frequently separated to some distance from each other, and much curved, so as to offer considerable resistance in the operation of extraction.*

Structure.—The base of the crown of each tooth is hollowed in its interior into a small cavity which is continuous with a canal passing through the middle of each fang. The cavity and canal, or canals,

* See an excellent practical work, "On the Structure, Economy, and Pathology of the Teeth," by Mr. Lintott.
constitute the cavitas pulpaë, and contain a soft cellulo-vascular organ, the pulp, which receives its supply of vessels and nerves through the small opening at the apex of each root. Mr. Nasmyth, to whose investigations science is so much indebted for our present knowledge of the intimate structure and development of the teeth, has observed with regard to the pulp, that it is composed of two different tissues, vascular and reticular, the former being an intricate web of minute vessels terminating in simple capillary loops, the latter a network of nucleated cells in which calcareous salts are gradually deposited, and which by a systematic continuance of that process are gradually converted into ivory. This process naturally takes place at the surface of the pulp, and as the pulp is thus robbed of its cells, new cells are produced by the capillary plexus to supply their place, and be in their turn similarly transformed.

A tooth is composed of three distinct structures, ivory or tooth-bone, enamel, and a cortical substance or cementum. The ivory consists of very minute, tapering, and branching fibres embedded in a dense homogeneous, interfibrous substance. The fibres commence by their larger ends at the walls of the cavitas pulpaë and pursue a radiating and serpentine course towards the periphery of the tooth, where they terminate in ramifications of extreme minuteness. These fibres, heretofore considered to be hollow tubuli, have been shewn by Mr. Nasmyth to be rows of minute opake bodies, arranged in a linear series (bacated fibres, Nasmyth), to be, in fact, the nuclei of the ivory cells, the interfibrous substance being the rest of the cell filled with calcareous matter. In the natural state of the tooth all trace of the parietes or mode of connection of the cells is lost, but after steeping in weak acid the cellular network is perfectly distinct.

The enamel forms a crust over the whole exposed surface of the crown of the tooth to the commencement of its root; it is thickest over the upper part of the crown, and becomes gradually thinner as it approaches the neck. It is composed of minute hexagonal crystalline fibres, resting by one extremity against the surface of the ivory, and constituting by the other the free surface of the crown. The fibres examined on the face of a longitudinal section have a waving arrangement, and consist, like those of ivory, of cells connected by their surfaces and ends and filled with calcareous substance. When the latter is removed by weak acid the enamel presents a delicate cellular network of animal matter.

The cortical substance, or cementum, (substantia ostoidæ,) forms a thin coating over the root of the tooth, from the termination of the enamel to the opening in the apex of the fang. In structure it is analogous to bone, and is characterized by the presence of numerous calcigerous cells and tubuli. The cementum increases in thickness with the advance of age, and gives rise to those exostosed appearances occasionally seen in the teeth of very old persons, or in those who have taken much mercury. In old age the cavitas pulpaë is often found filled up and obliterated by osseous substance analogous to the
cementum. Mr. Nasmyth has shewn that this, like the other structures composing a tooth, is formed of cells having a reticular arrangement.

**Development.**—The development of the teeth in the human subject has been successfully investigated by Mr. Goodsir, to whose interesting researches I am indebted for the following narrative:*—

The inquiries of Mr. Goodsir commenced as early as the sixth week after conception, in an embryo, which measured seven lines and a half in length and weighed fifteen grains. At this early period each upper jaw presents two semicircular folds around its circumference; the most external is the true lip; the internal, the rudiment of the palate; and between these is a deep groove, lined by the common mucous membrane of the mouth. A little later, a ridge is developed from the floor of this groove in a direction from behind forwards, this is the rudiment of the external alveolus; and the arrangement of the appearances from without inwards at this period is the following:—Most externally and forming the boundary of the mouth, is the lip; next we find a deep groove, which separates the lip from the future jaw; then comes the external alveolar ridge; fourthly, another groove, in which the germs of the teeth are developed, the primitive dental groove; fifthly, a rudiment of the internal alveolar ridge; and, sixthly, the rudiment of the future palate bounding the whole internally. At the seventh week the germ of the first deciduous molar of the upper jaw has made its appearance, in the form of a “simple, free, granular papilla” of the mucous membrane, projecting from the floor of the primitive dental groove; at the eighth week, the papilla of the canine tooth is developed; at the ninth week, the papillae of the four incisors (the middle preceding the lateral) appear; and at the tenth week the papilla of the second molar is seen behind the anterior molar in the primitive dental groove. So that at this early period, viz. the tenth week, the papillae or germs of the whole ten deciduous teeth of the upper jaw are quite distinct. Those of the lower jaw are a little more tardy; the papilla of the first molar is merely a slight bulging at the seventh week, and the tenth papilla is not apparent until the eleventh week.

From about the eighth week the primitive dental groove becomes contracted before and behind the first deciduous molar, and laminae of the mucous membrane are developed around the other papillæ, which increase in growth and enclose the papillæ in follicles with open mouths. At the tenth week the follicle of the first molar is completed, then that of the canine; during the eleventh and twelfth weeks the follicles of the incisors succeed, and at the thirteenth week the follicle of the posterior deciduous molar.

During the thirteenth week the papillæ undergo an alteration of form, and assume the shape of the teeth they are intended to repre-

---

sent. And at the same time small membranous processes are developed from the mouths of the follicles; these processes are intended to serve the purpose of opercula to the follicles, and they correspond in shape with the form of the crowns of the appertaining teeth. To the follicles of the incisor teeth there are two opercula; to the canine, three; and to the molars a number relative to the number of their tubercles, either four or five. During the fourteenth and fifteenth weeks the opercula have completely closed the follicles, so as to convert them into dental sacs, and at the same time the papillae have become pulps.

The deep portion of the primitive dental groove, viz. that which contains the dental sacs of the deciduous teeth, being thus closed in, the remaining portion, that which is nearer the surface of the gum, is still left open, and to this Mr. Good sir has given the title of secondary dental groove; as it serves for the development of all the permanent teeth, with the exception of the anterior molars. During the fourteenth and fifteenth weeks small lunated inflections of the mucous membrane are formed, immediately to the inner side of the closing opercula of the deciduous dental follicles, commencing behind the incisors and proceeding onwards through the rest; these are the rudiments of the follicles or cavities of reserve of the four permanent incisors, two permanent canines, and the four bicuspides. As the secondary dental groove gradually closes, these follicular inflections of the mucous membrane are converted into closed cavities of reserve, which recede from the surface of the gum and lie immediately to the inner side and in close contact with the dental sacs of the deciduous teeth, being enclosed in their submucous cellular tissue. At about the fifth month the anterior of these cavities of reserve dilate at their distal extremities, and a fold or papilla projects into their fundus, constituting the rudiment of the germ of the permanent tooth; at the same time two small opercular folds are produced at their proximal or small extremities, and convert them into true dental sacs.

During the fifth month the posterior part of the primitive dental groove behind the sac of the last deciduous tooth has remained open, and in it has developed the papilla and follicle of the first permanent molar. Upon the closure of this follicle by its opercula, the secondary dental groove upon the summit of its crown forms a large cavity of reserve, lying in contact with the dental sac upon the one side and with the gum upon the superficial side. At this period the deciduous teeth, and the sacs of the ten anterior permanent teeth, increase so much in size, without a corresponding lengthening of the jaws, that the first permanent molars are gradually pressed backwards and upwards into the maxillary tuberosity in the upper jaw, and into the base of the coronoid process of the lower jaw; a position which they occupy at the eighth and ninth months of fetal life. In the infant of seven or eight months the jaws have grown in length, and the first permanent molar returns to its proper position in the dental range. The cavity of reserve, which has been previously elongated by the
forward movement of the first permanent molar, now dilates into the
cavity which that tooth has just quitted; a papilla is developed from
its fundus, the cavity becomes constricted, and the dental sac of the
second molar tooth is formed, still leaving a portion of the great
cavity of reserve in connection with the superficial side of the sac.
As the jaws continue to grow in length, the second permanent dental
sac descends from its elevated position and advances forwards into
the dental range, following the same curve with the first permanent
molar. The remainder of the cavity of reserve, already lengthened
backwards by the previous position of the second molar, again dilates
for the last time, develops a papilla and sac in the same manner with
the preceding, and forms the third permanent molar or wisdom tooth,
which at the age of nineteen or twenty, upon the increased growth
of the jaw, follows the course of the first and second molars into the
dental range.

From a consideration of the foregoing phenomena, Mr. Goodsir has
divided the process of dentition into three natural stages:—1. folli-
cular; 2. saccular; 3. eruptive. The first, or follicular stage, he
makes to include all the changes which take place from the first
appearance of the dental groove and papillæ to the closure of their
folllicles; occupying a period which extends from the sixth week to
the fourth or fifth month of intra-uterine existence. The second, or
saccular stage, comprises the period when the follicles are shut sacs,
and the included papillæ pulps; it commences at the fourth and fifth
months of intra-uterine existence, and terminates for the median
incisors, at the seventh or eighth month of infantile life, and for
the wisdom teeth at about the twenty-first year. The third, or
eruptive stage, includes the completion of the teeth, the eruption
and shedding of the temporary set, the eruption of the permanent,
and the necessary changes in the alveolar processes. It extends
from the seventh month till the twenty-first year.

"The anterior permanent molar," says Mr. Goodsir, "is the most
remarkable tooth in man, as it forms a transition between the milk
and the permanent set." If considered anatomically, i. e. in its de-
velopment from the primitive dental groove, by a papilla and follicle,
"it is decidedly a milk tooth;" if physiologically, "as the most
efficient grinder in the adult mouth, we must consider it a permanent
tooth." "It is a curious circumstance, and one which will readily
suggest itself to the surgeon, that laying out of view the wisdom
teeth, which sometimes decay at an early period from other causes,
the anterior molars are the permanent teeth which most frequently
give way first, and in the most symmetrical manner and at the same
time, and frequently before the milk set."

Growth of Teeth.—Immediately that the dental follicles have been
closed by their opercula, the pulps become moulded into the form of
the future teeth; and the bases of the molars divided into two or
three portions representing the future fangs. The dental sac is com-
posed of two layers, an internal or vascular layer, which was originally
a part of the mucous surface of the mouth, and a cellulo-fibrous layer,
analogous to the corium of the mucous membrane. Upon the forma-
tion of this sac by the closure of the follicle, the mucous membrane
resembles a serous membrane in being a shut sac, and may be con-
sidered as consisting of a tunica propria, which invests the pulp; and
a tunica reflexa, which is adherent by its outer surface with the
structures in the jaw, and by the inner surface is free, being separated
from the pulp by an intervening cavity. As soon as the moulding of
the pulp has commenced, this cavity increases and becomes filled
with a gelatinous granular substance, the enamel organ, which is
adherent to the whole internal surface of the tunica reflexa, but not
to the tunica propria and pulp. At the same period, viz. during the
fourth or fifth month, a thin lamina of ivory is formed by the pulp,
and occupies its most prominent point: if the tooth be incisor or
canine, the newly formed layer has the figure of a small hollow cone;
if molar, there will be four or five small cones corresponding with
the number of tubercles on its crown. These cones are united by
the formation of additional layers, the pulp becomes gradually sur-
rounded and diminishes in size, evolving fresh layers during its
retreat into the jaws until the entire tooth with its fangs is completed,
and the small cavitas pulpeae of the perfect tooth alone remains,
communicating through the opening in the apex of each fang with the
dental vessels and nerves. The number of roots appears to depend
upon the number of nervous filaments sent to each pulp. When the
formation of the ivory has commenced, the enamel organ becomes
transformed into a laminated tissue, corresponding with the direction
of the fibres of the enamel, and the crystalline substance of the enamel
is secreted into its meshes by the vascular lining of the sac.
The cementum appears to be formed at a later period of life, either
by a deposition of osseous substance by that portion of the dental sac,
which continues to enclose the fang, and acts as its periosteum, or by
the conversion of that membrane itself into bone; the former supposi-
tion is the more probable.
The formation of ivory commences in the first permanent molar pre-
viously to birth.

Eruption.—When the crown of the tooth has been formed and
coated with enamel, and the fang has grown to the bottom of its socket
by the progressive lengthening of the pulp, the formation of ivory,
and the adhesion of the ivory to the contiguous portion of the sac, the
pressure of the socket causes the reflected portion of the sac and the
edge of the tooth to approach, and the latter to pass through the gum.
The sac has thereby resumed * its original follicular condition, and
has become continuous with the mucous membrane of the mouth. The
opened sac now begins to shorten more rapidly than the fang lengthens,
and the tooth is quickly drawn upwards by the contraction, leaving a

* Mr. Nasymth is of opinion that it is "by a process of absorption, and not
of disruption, that the tooth is emancipated." Medico-chirurgical Transac-
tions. 1839.
space between the extremity of the unfinished root and the bottom of the socket, in which the growth and completion of the fang is more speedily effected.

During the changes which have here been described as taking place among the dental sacs contained within the jaws, the septa between the sacs, which at first were composed of spongy tissue, soon became fibrous, and were afterwards formed of bone, which was developed from the surface and proceeded by degrees more deeply into the jaws, to constitute the alveoli. The sacs of the ten anterior permanent teeth, at first enclosed in the submucous cellular tissue of the deciduous dental sacs, and received during their growth into crypts situated behind the deciduous teeth advanced by degrees beneath the fangs of those teeth, and became separated from them by distinct osseous alveoli. The necks of the sacs of the permanent teeth, by which they originally communicated with the mucous lining of the secondary groove, still exist, in the form of minute obliterated cords, separated from the deciduous teeth by their alveolus, but communicating through a minute osseous canal with the fibrous tissue of the palate, immediately behind the corresponding deciduous teeth. "These cords and foramina are not obliterated in the child," says Mr. Goodsr, "either because the cords are to become useful as 'gubernacula' and the canals as 'itinera dentium'; or, much more probably, in virtue of a law, which appears to be a general one in the development of animal bodies, viz. that parts, or organs, which have once acted an important part, however atrophied they may afterwards become, yet never altogether disappear, so long as they do not interfere with other parts or functions."

Succession.—The periods of appearance of the teeth are extremely irregular; it is necessary, therefore, to have recourse to an average, which, for the temporary teeth, may be stated as follows, the teeth of the lower jaw preceding those of the upper by a short interval:—

7th month, two middle incisors. 18th month, canine.
9th month, two lateral incisors. 24th month, two last molares.
12th month, first molares.

The periods for the permanent teeth are,

6½ year, first molares. 10th year, second bicuspides.
7th year, two middle incisors. 11th to 12th year, canine.
8th year, two lateral incisors. 12th to 13th year, second molares.
9th year, first bicuspides. 17th to 21st year, last molares.

OS HYOIDES.

The os hyoides forms the second arch developed from the cranium, and gives support to the tongue, and attachment to numerous muscles in the neck. It is named from its resemblance to the Greek letter υ, and consists of a central portion or body, of two larger cornua, which
project backwards from the body; and two lesser cornua, which ascend from the angles of union between the body and the greater cornua.

The body is somewhat quadrilateral, rough and convex on its antero-superior surface, by which it gives attachment to muscles; concave and smooth on the postero-inferior surface, by which it lies in contact with the thyro-hyoidean membrane. The greater cornua are flattened from above downwards, and terminated posteriorly by a tubercle; and the lesser cornua, conical in form, give attachment to the stylo-hyoid ligaments. In early age and in the adult, the cornua are connected with the body by cartilaginous surfaces and ligamentous fibres; but in old age they become united by bone.

*Development.*—By five centres, one for the body, and one for each cornu. Ossification commences in the greater cornua during the last month of foetal life, and in the lesser cornua and body soon after birth.

*Attachment of Muscles.*—To eleven pairs; sterno-hyoid, thyro-hyoid, omo-hyoid, pulley of the digastricus, stylo-hyoid, mylo-hyoid, genio-hyoid, genio-hyo-glossus, hyo-glossus, lingualis, and middle constrictor of the pharynx. It also gives attachment to the stylo-hyoid, thyro-hyoid, and hyo-epiglottic ligaments, and to the thyro-hyoidean membrane.

**THORAX AND UPPER EXTREMITY.**

The bones of the thorax are the sternum and ribs; and, of the upper extremity, the clavicle, scapula, humerus, ulna and radius, bones of the carpus, metacarpus, and phalanges.

**Sternum.**—The sternum (fig. 33) is situated in the middle line of the front of the chest, and is oblique in direction, the superior end lying within a few inches of the vertebral column, and the inferior being projected forwards so as to be placed at a considerable distance from the spine. The bone is flat or slightly concave in front, and marked by five transverse lines which indicate its original subdivision into six pieces. It is convex behind, broad and thick above, flattened and pointed below, and is divisible in the adult into three pieces, superior, middle, and inferior.

The *superior piece* or manubrium is nearly quadrilateral; it is broad and thick above, where it presents a concave border (incisura semi-

---

lunaris), and narrow at its junction with the middle piece. At each superior angle is a deep articular depression (incisura clavicularis) for the clavicle, and on either side two notches, for the articulation of the cartilage of the first rib, and one half of the second.

The middle piece or body, considerably longer than the superior, is broad in the middle, and somewhat narrower at each extremity. It presents at either side six articular notches, for the lower half of the second rib, the four next ribs, and the upper half of the seventh. This piece is sometimes perforated by an opening of various magnitude resulting from arrest of development.

The inferior piece (ensiform or xiphoid cartilage) is the smallest of the three, often merely cartilaginous, and very various in appearance, being sometimes pointed, at other times broad and thin, and at other times again, perforated by a round hole, or bifid. It presents a notch at each side for the articulation of the lower half of the cartilage of the seventh rib.

Development.—By a variable number of centres, generally ten, namely, two for the manubrium; one (sometimes two) for the first piece of the body, two for each of the remaining pieces, and one for the ensiform cartilage. Ossification commences towards the end of the fifth month in the manubrium, the two pieces for this part being placed one above the other. At about the same time the centres for the first and second pieces of the body are apparent; the centres for the third piece of the body appear a few months later, and those for the fourth piece soon after birth. The osseous centre for the ensiform cartilage, is so variable in its advent, that it may be present at any period between the third and eighteenth year. The double centres for the body of the sternum are disposed side by side in pairs, and it is the irregular union of these pairs in the last three pieces of the body that gives rise to the large aperture occasionally seen in the sternum towards its lower part. Union of the pieces of the sternum commences from below and proceeds upwards; the fourth and the third unite at about puberty, the third and the second between twenty and twenty-five, and the second and the first between twenty-five and thirty. The ensiform appendix becomes joined to the body of the sternum at forty or fifty years; and the manubrium to the body only in very old age. Two small pisiform pieces have been described by Beclard and Breschet, as being situated upon and somewhat behind each extremity of the incisura semilunaris of the upper border of the manubrium. These pre-sternal or supra-sternal pieces which are by no means constant, appear at about the thirty-fifth year. Beclard considers them to be the analogue of the fourchette of birds, and Breschet as the sternal ends of the cervical rib.

Articulations.—With sixteen bones; viz. with the clavicle and the seven true ribs, at each side.

Attachment of Muscles.—To nine pairs and one single muscle; viz. to the pectoralis major, sterno-mastoid, sterno-hyoid, sterno-thyroid,
triangularis sterni, aponeurosis of the obliquus externus, internus, and transversalis muscles, rectus, and diaphragm.

RIBS.—The ribs are twelve in number at each side; the first seven are connected with the sternum, and hence named sternal or true ribs; the remaining five are the aternal or false ribs; and the last two shorter than the rest, and free at their extremities, are the floating ribs.

Fig. 33.*

The ribs increase in length from the first to the eighth, whence they again diminish to the twelfth; in breadth they diminish gradually from the first to the last, and with the exception of the last two are broader at the anterior than at the posterior end. The first rib is horizontal in its direction; all the rest are oblique, so that the anterior extremity falls considerably below the posterior. Each rib presents an external and internal surface, a superior and inferior border,

* An anterior view of the thorax. 1. The superior piece of the sternum. 2. The middle piece. 3. The inferior piece, or ensiform cartilage. 4. The first dorsal vertebra. 5. and two extremities; it is curved to correspond with the arch of the thorax, and twisted upon itself, so that, when laid on its side, one end is tilted up, while the other rests upon the surface.

The external surface is convex, and marked by the attachment of muscles; the internal is flat, and corresponds with the pleura; the superior border is rounded; and the inferior sharp and grooved upon its inner side, for the attachment of the intercostal muscles.* Near its vertebral extremity, the rib is suddenly bent upon itself; and opposite the bend, upon the external surface, is a rough oblique ridge, which gives attachment to a tendon of the sacro-lumbalis muscle, and is called the angle. The distance between the vertebral extremity and the angle increases gradually, from the second to the eleventh rib. Beyond the angle is a rough elevation, the tubercle; and immediately at the base and under side of the tubercle a smooth surface for articulation with the extremity of the transverse process of the corresponding vertebra. The vertebral end of the rib is somewhat expanded, and is termed the head, and that portion between the head and the tubercle is the neck. On the extremity of the head is an oval smooth surface divided by a transverse ridge into two facets for articulation with two contiguous vertebrae. The posterior surface of the neck is rough, for the attachment of the middle costo-transverse ligament; and upon its upper border is a crest, which gives attachment to the anterior costo-transverse ligament. The sternal extremity is flattened, and presents an oval depression, into which the costal cartilage is received.

The ribs that demand especial consideration are the first, tenth, eleventh, and twelfth.

The first is the shortest rib; it is broad and flat, and placed horizontally at the upper part of the thorax, the surfaces looking upwards and downwards, in place of forwards and backwards as in the other ribs. At about the anterior third of the upper surface of the bone, and near its internal border, is a tubercle which gives attachment to the scalenus anterior muscle, and immediately before and behind this tubercle, a shallow oblique groove, the former for the subclavian vein, and the latter for the subclavian artery. Near the posterior extremity of the bone is a thick and prominent tubercle, with a smooth articular surface for the transverse process of the first dorsal vertebra. There is no angle. Beyond the tuberosity is a narrow constricted neck; and at the extremity, a head, presenting a single articular surface. The second rib approaches in some of its characters to the first.

The tenth rib has a single articular surface on its head.

The eleventh and twelfth have each a single articular surface on the head, no neck or tubercle, and are pointed at the free extremity. The eleventh has a slight ridge, representing the angle, and a shallow groove on the lower border; the twelfth has neither.

* This groove is commonly described as supporting the intercostal artery vein and nerve, but this is not the case.
Costal Cartilages.—The costal cartilages serve to prolong the ribs forwards to the anterior part of the chest, and contribute mainly to the elasticity of the thorax. They are broad at their attachment to the ribs, and taper slightly towards the opposite extremity; they diminish gradually in breadth from the first to the last; in length they increase from the first to the seventh, and then decrease to the last. The cartilages of the first two ribs are horizontal in direction, the rest incline more and more upwards. In advanced age the costal cartilages are more or less converted into bone, this change taking place earlier in the male than in the female.

The first seven cartilages articulate with the sternum; the three next, with the lower border of the cartilage immediately preceding, while the last two lie free between the abdominal muscles. All the cartilages of the false ribs terminate by pointed extremities.

Development.—The ribs are developed by three centres; one for the central part, one for the head, and one for the tubercle. The last two have no centre for the tubercle. Ossification commences in the body somewhat before its appearance in the vertebra; the epiphysal centres for the head and tubercle appear between sixteen and twenty, and are consolidated with the rest of the bone at twenty-five.

Articulations.—Each rib articulates with two vertebrae, and one costal cartilage, with the exception of the first, tenth, eleventh, and twelfth, which articulate each with a single vertebra only.

Attachment of Muscles.—To the ribs and their cartilages are attached twenty-two pairs, and one single muscle. To the cartilages, the subclavius, sterno-thyroid, pectoralis major, internal oblique, rectus, transversalis, diaphragm, triangularis sterni, internal and external intercostals. To the ribs, the intercostal muscles, scalenus anticus, scalenus posticus, pectoralis minor, serratus magnus, obliquis externus, obliquus internus, latissimus dorsi, quadratus lumborum, serratus posticus superior, serratus posticus inferior, sacro-lumbalis, longissimus dorsi, cervicalis ascendens, levatores costarum, transversalis, and diaphragm.

Clavicle.—The clavicle is a long bone shaped like the italic letter S, and extended across the upper part of the side of the chest from the upper piece of the sternum to the point of the shoulder, where it articulates with the scapula. In position it is very slightly oblique, the sternal end being somewhat lower and more anterior than the scapular, and the curves are so disposed that at the sternal end the convexity, and at the scapular the concavity, is directed forwards. The sternal half of the bone is rounded or irregularly quadrilateral, and terminates in a broad articular surface. The scapular half is flattened from above downwards, and broad at its extremity, the articular surface occupying only part of its extent. The upper surface is smooth and convex, and partly subcutaneous; while the under surface is rough and depressed, for the insertion of the subclavius muscle. At the sternal extremity of the under surface is a very rough prominence, which gives attachment to the rhomboid ligament; and at the other extremity a rough
SCAPULA.

tubercle and ridge, for the coraco-clavicular ligament. The opening for the nutritious vessels is seen upon the under surface of the bone.

Development.—By two centres; one for the shaft and one for the sternal extremity; the former appearing before any other bone of the skeleton, the latter between fifteen and eighteen.

Articulations.—With the sternum and scapula.

Attachment of Muscles.—To six; the sterno-mastoid, trapezius, pectoralis major, deltoid, subclavius, and sterno-hyoid.

SCAPULA.—The scapula is a flat triangular bone, situated upon the posterior aspect and side of the thorax occupying the space from the second to the seventh rib. It is divisible into an anterior and posterior surface, superior, inferior, and posterior border, anterior, superior, and inferior angle, and processes.

The anterior surface, or subscapular fossa, is concave and irregular, and marked by several oblique ridges which have a direction upwards and outwards. The whole concavity is occupied by the subscapularis muscle, with the exception of a small triangular portion near the superior angle. The posterior surface or dorsum is convex, and unequally divided into two portions by the spine; that portion above the spine is the supra-spinous fossa; and that below, the infra-spinous fossa.

The superior border is the shortest of the three; it is thin and concave, and terminated at one extremity by the superior angle, and at the other by the coracoid process. At its inner termination, and formed partly by the base of the coracoid process, is the supra-scapular notch, for the transmission of the supra-scapular nerve.

The inferior or axillary border is thick, and marked by several grooves and depressions; it terminates superiorly at the glenoid cavity, and inferiorly at the inferior angle. Immediately below the glenoid cavity is a rough ridge, which gives origin to the long head of the triceps muscle. Upon the posterior surface of the border is a depression for the teres minor; and upon its anterior surface a deeper groove for the teres major; near the inferior angle is a projecting lip, which increases the surface of origin of the latter muscle.

The posterior border or base, the longest of the three, is turned towards the vertebral column. It is intermediate in thickness between the superior and inferior, and convex, being considerably inflected outwards towards the superior angle.

The anterior angle is the thickest part of the bone, and forms the head of the scapula; it is immediately surrounded by a constricted portion, the neck. The head presents a shallow pyriform articular surface, the glenoid cavity, having the pointed extremity upwards; and at its apex is a rough depression, which gives attachment to the long tendon of the biceps. The superior angle is thin and pointed. The inferior angle is thick, and smooth upon the external surface for the origin of the teres major and for a large bursa over which the upper border of the latissimus dorsi muscle plays.

The spine of the scapula, triangular in form, crosses the upper part of
dorsum; it commences at the posterior border by a smooth triangular surface over which the trapezius glides upon a bursa, and terminates at the point of the shoulder in the acromion process. The upper border of the spine is rough and subcutaneous, and gives attachment by two projecting lips to the trapezius and deltoid muscles; the surfaces of the spine enter into the formation of the supra and infra-spinous fossae. The nutritious foramina of the scapula are situated in the base of the spine.

The acromion is somewhat triangular and flattened from above downwards; it overhangs the glenoid cavity, the upper surface being rough and subcutaneous, the lower smooth and corresponding with the shoulder-joint. Near its extremity, upon the anterior border, is an oval articular surface, for the end of the clavicle.

The coracoid process is a thick, round, and curved process of bone, arising from the upper part of the neck of the scapula, and overarchin the glenoid cavity. It is about two inches in length and very strong; it gives attachment to several ligaments and muscles.

Development.—By six centres; one for the body, one for the coracoid process, two for the acromion, one for the inferior angle, and one for the posterior border. The ossific centre for the body appears in the infra-spinous fossa at about the same time with the ossification of the vertebrae; for the coracoid process during the first year; the acromion process at puberty; the inferior angle in the fifteenth year; and the posterior border at seventeen or eighteen. Union between the

One of the nutritious foramina. 14. The coracoid process.
coracoid process and body takes place during the fifteenth year; the bone is not complete till manhood.

Articulations.—With the clavicle and humerus.

Attachment of Muscles.—To sixteen; by its anterior surface to the subscapularis; posterior surface, supra-spinatus and infra-spinatus; superior border, omo-hyoid; posterior border, levator anguli scapulae, rhomboideus minor, rhomboideus major, and serratus magnus; anterior border, long head of the triceps, teres minor, and teres major; upper angle of the glenoid cavity, to the long tendon of the biceps; spine and acromion, to the trapezius and deltoid; coracoid process, to the pectoralis minor, short head of the biceps, and coraco-brachialis. The ligaments attached to the coracoid process are, the coracoid, coraco-clavicular, and coraco-humeral, and the costo-coracoid membrane.

Humerus.—The humerus is a long bone divisible into a shaft and two extremities.

The superior extremity presents a rounded head; a constriction immediately around the base of the head, the neck; a greater and a lesser tuberosity. The greater tuberosity is situated most externally, and is separated from the lesser by a vertical furrow, the bicipital groove, which lodges the long tendon of the biceps. The edges of this groove below the head of the bone are raised and rough, and are called the anterior and posterior bicipital ridge; the former serves for the insertion of the pectoralis major muscle, and the latter of the latissimus dorsi and teres major.

The constriction of the bone below the tuberosities is the surgical neck, and is so named, in contradistinction to the true neck, from being the seat of the accident called by surgical writers fracture of the neck of the humerus.

The shaft of the bone is prismoid at its upper part, and flattened from before backwards below. Upon its outer side, at about its middle, is a rough triangular eminence, which gives insertion to the deltoid; and immediately on each side of this eminence is a smooth depression, corresponding with the two heads of the brachialis anticus. Upon the inner side of the middle of the shaft is a ridge, for the attachment of the coraco-brachialis muscle; and behind, an oblique and shallow groove, which lodges the musculo-spiral nerve and superior profunda artery. The foramen for the medullary vessels is situated upon the inner surface of the shaft of the bone a little below the coraco-brachial ridge; it is directed downwards.

The lower extremity is flattened from before backwards, and is terminated inferiorly by a long articular surface, divided into two parts by an elevated ridge. The external portion of the articular surface is a rounded protuberance, eminentia capitata, which articulates with the cup-shaped depression on the head of the radius; the internal portion is a concave and pulley-like surface, trochlea, which articulates with the ulna. Projecting beyond the articular surface on each side are
the external and internal condyle, the latter being considerably the longer; and running upwards from the condyles upon the borders of the bone are the condyloid ridges, of which the external is the most prominent. Immediately in front of the trochlea is a small depression for receiving the coronoid process of the ulna during flexion of the forearm; and immediately behind it a large and deep fossa, for containing the olecranon process in extension.

Development. — By seven centres; one for the shaft, one for the head, one for the tuberosities, one for the eminentia capitata, one for the trochlea, and one for each condyle, the internal preceding the external. Ossification commences in the diaphysis of the humerus soon after the clavicle; in the head and tuberosities, during the second and third years of infantile life; in the eminentia capitata and trochlea during the third and sixth years; and in the condyles during the twelfth and fifteenth. The entire bone is consolidated at twenty.

Articulations. — With the glenoid cavity of the scapula, and with the ulna and radius.

Attachment of Muscles.—To twenty-four; by the greater tuberosity to the supra-spinatus, infra-spinatus, and teres minor; lesser tuberosity, subscapularis; anterior bicipital ridge, pectoralis major; posterior bicipital ridge and groove, teres major and latissimus dorsi; shaft, external and internal heads of the triceps, deltoid, coracobrachialis, and brachialis anticus; external condyloid ridge and condyle (condylus extensorius), extensors and supinators of the forearm, viz. supinator longus, extensor carpi radialis longior, extensor carpi radialis brevior, extensor communis digitorum, extensor minimi digiti, extensor carpi ulnaris, anconeus, and supinator brevis; internal condyle (condylus flexorius), flexors and one pronator, viz. pronator radii teres, flexor carpi radialis, palmaris longus, flexor sublimis digitorum, and flexor carpi ulnaris.

The external condyle. 14. The internal condyle. 15. The external condyloid ridge. 16. The internal condyloid ridge. 17. The fossa for the coronoid process of the ulna.
ULNA.—The ulna is a long bone, divisible into a shaft and two extremities. The upper extremity is large, and forms principally the articulation of the elbow; while the lower extremity is small, and excluded from the wrist-joint by an inter-articular fibro-cartilage.

The superior extremity presents a semilunar concavity of large size, the greater sigmoid notch, for articulation with the humerus; and upon the outer side a lesser sigmoid notch, which articulates with the head of the radius. Bounding the greater sigmoid notch posteriorly is the olecranon process; and, overhanging it in front, a pointed eminence with a rough triangular base, the coronoid process. Behind the lesser sigmoid notch, and extending downwards on the side of the olecranon, is a triangular uneven surface, for the anconeus muscle; and upon the posterior surface of the olecranon a smooth triangular surface, which is subcutaneous.

The shaft is prismoid in form, and presents three surfaces, anterior, posterior, and internal; and three borders. The anterior surface is occupied by the flexor profundus digitorum for the upper three-fourths of its extent; and below by a depression, for the pronator quadratus muscle. A little above its middle is the nutritious foramen, which is directed upwards. Upon the posterior surface at the upper part of the bone is the triangular uneven depression for the anconeus muscle, bounded inferiorly by an oblique ridge which runs downwards from the posterior extremity of the lesser sigmoid notch. Below the ridge the surface is marked into several grooves, for the attachment of the extensor ossis metacarpi, extensor secundi internodii, and extensor indicis muscle. The internal surface is covered in for the greater part of its extent by the flexor profundus digitorum. The anterior border is rounded, and gives origin by its lower fourth to the pronator quadratus; the posterior is more prominent, and affords attachment to the flexor carpi ulnaris and extensor carpi ulnaris. At its upper extremity it expands into the triangular subcutaneous surface of the olecranon. The external or radial border is sharp and prominent, for the attachment of the interosseous membrane.

The lower extremity terminates in a small rounded head, capitulum ulna, from the side of which projects the styloid process. The latter presents a deep notch at its base for the attachment of the apex of the triangular interarticular cartilage, and by its point gives attachment to the internal lateral ligament. Upon the posterior surface of the head is a groove, for the tendon of the extensor carpi ulnaris; and upon the side opposite to the styloid process a smooth surface, for articulation with the side of the radius.

Development.—By three centres; one for the shaft, one for the inferior extremity, and one for the olecranon. Ossification commences in the ulna shortly after the humerus and radius; the two ends of the bone are cartilaginous at birth. The centre for the lower end appears at about the fifth, and that for the olecranon about the seventh year. The bone is completed at about the twentieth year.

Articulations.—With two bones; the humerus and radius; it is se-
parated from the cuneiform bone of the carpus by the triangular inter-articular cartilage.

Attachment of Muscles.—To twelve; by the olecranon, to the triceps extensor cubiti, one head of the flexor carpi ulnaris, and the anconeus; by the coronoid process, to the brachialis anticus, pronator radii teres, flexor sublimis digitorum, and flexor profundus digitorum; by the shaft, to the flexor profundus digitorum, flexor carpi ulnaris, pronator quadratus, anconeus, extensor carpi ulnaris, extensor ossis metacarpi pollicis, extensor secundii internodii pollicis, and extensor indicis.

Radius.—The radius is the rotatory bone of the fore-arm; it is divisible into a shaft and two extremities: unlike the ulna, its upper extremity is small, and merely accessory to the formation of the elbow-joint; while the lower extremity is large, and forms almost solely the joint of the wrist.

The superior extremity presents a rounded head, depressed upon its upper surface into a shallow cup. Around the margin of the head is a smooth articular surface, which is broad on the inner side, where it articulate with the lesser sigmoid notch of the ulna, and narrow in the rest of its circumference, to play in the orbicular ligament. Beneath the head is a round constricted neck; and beneath the neck, on its internal aspect, a prominent process, the tuberosity. The surface of the tuberosity is partly smooth, and partly rough; rough below, where it receives the attachment of the tendon of the biceps; and smooth above, where a bursa is interposed between the tendon and the bone.

The shaft of the bone is prismatic, and presents three surfaces. The anterior surface is somewhat concave superiorly, where it lodges the flexor longus pollicis; and flat below, where it supports the pronator quadratus. At about the upper third of this surface is the nutritious foramen, which is directed upwards. The posterior surface is

round above, where it supports the supinator brevis muscle, and marked by several shallow oblique grooves below, which afford attachment to the extensor muscles of the thumb. The external surface is rounded and convex, and marked by an oblique ridge, which extends from the tuberosity to the styloid process at the lower extremity of the bone. Upon the inner margin of the bone is a sharp and prominent crest, which gives attachment to the interosseous membrane. The lower extremity of the radius is broad and triangular, and provided with two articular surfaces; one at the side of the bone, which is concave to receive the rounded head of the ulna; the other at the extremity, and marked by a slight ridge into two facets, one external and triangular, corresponding with the scaphoid; the other square, with the semilunar bone. Upon the outer side of the extremity is a strong conical projection, the styloid process, which gives attachment by its base to the tendon of the supinator longus, and by its apex to the external lateral ligament of the wrist joint. The inner edge of the articular surface affords attachment to the base of the inter-articular cartilage of the ulna.

Immediately in front of the styloid process is a groove, which lodges the tendons of the extensor ossis metacarpi pollicis, and extensor primi internodii; and behind the process a broader groove, for the tendons of the extensor carpi radialis longior and brevior, and extensor secundii internodii; behind this is a prominent ridge, and a deep and narrow groove, for the tendon of the extensor indicis; and still farther back part of a broad groove, completed by the ulna, for the tendons of the extensor communis digitorum.

Development.—By three centres; one for the shaft, and one for each extremity. Ossification commences in the shaft soon after the humerus, and before that in the ulna. The inferior centre appears during the second year, and the superior about the seventh. The bone is perfected at twenty.

Articulations.—With four bones; humerus, ulna, scaphoid, and semilunar.

Attachment of Muscles.—To nine; by the tuberosity to the biceps; by the oblique ridge to the supinator brevis, pronator radii teres, flexor sublimis digitorum and pronator quadratus; by the anterior surface, to the flexor longus pollicis and pronator quadratus; by the posterior surface, to the extensor ossis metacarpi pollicis, and extensor primi internodii; and by the styloid process, to the supinator longus.

Carpus.—The bones of the carpus are eight in number; they are arranged in two rows. In the first row, commencing from the radial side, are the os scaphoides, semilunare, cuneiforme, pisiforme; and in the second row, in the same order, the os trapezium, trapezoides, os magnum and unciforme.

The Scaphoid bone is named from bearing some resemblance to the shape of a boat, being broad at one end, and narrowed like a prow at the opposite, concave on one side, and convex upon the other. It
SCAPHOID BONE.—SEMILUNARE.

is, however, more similar in form to a cashew nut, flattened and concave upon one side. If carefully examined, it will be found to present a convex and a concave surface, a convex and a concave border, a broad end, and a narrow and pointed extremity, the tuberosity.

To ascertain to which hand the bone belongs, let the student hold it horizontally, so that the convex surface may look backwards (i.e. towards himself), and the convex border upwards: the broad extremity will indicate its appropriate hand; if it be directed to the right, the bone belongs to the right; and if to the left, to the left carpus.

Articulations.—With five bones; by its convex surface with the radius; by its concave surface, with the os magnum and semilunare; and by the extremity of its upper or dorsal border, with the trapezium and trapezoides.

Attachments.—By its tuberosity to the abductor pollicis, and anterior annular ligament.

The semilunar bone may be known by having a crescentic concavity, and a somewhat crescentic outline. It presents for examination four articular surfaces and two extremities; the articular surfaces are, one concave, one convex, and two lateral, one lateral surface being crescentic, the other nearly circular, and divided generally into two facets. The extremities are, one dorsal, which is quadrilateral, flat, and indented, for the attachment of ligaments; the other palmar, which is convex, rounded, and of larger size.

To determine to which hand it belongs, let the bone be held perpendicularly, so that the dorsal or flat extremity look upwards, and the convex side backwards (towards the holder). The circular lateral

The pisiforme, articulating with the cuneiforme only. T. The first bone of the second row, the trapezium, articulating with four bones. T. The second bone, the trapezoides, articulating also with four bones. M. The os magnum, articulating with seven. U. The uniciforme, articulating with five. The numerals, 1, 3, 1, 2, 1, on the metacarpal bones, refer to the number of their articulations with the carpal bones.
surface will point to the side corresponding with the hand to which the bone belongs.

Articulations.—With five bones, but occasionally with only four; by its convex surface, with the radius; by its concave surface, with the os magnum; by its crescentic lateral facet, with the scaphoid; and by the circular surface, with the cuneiform bone and with the point of the unciform. This surface is divided into two parts by a ridge when it articulates with the unciform as well as with the cuneiform bone.

The cuneiform bone, although somewhat wedge-shaped in form, may be best distinguished by a circular and isolated facet, which articulates with the pisiform bone. It presents for examination three surfaces, a base, and an apex. One surface is very rough and irregular; the opposite forms a concave articular surface, while the third is partly rough and partly smooth, and presents that circular facet which is characteristic of the bone. The base is an articular surface, and the apex is rough and pointed.

To distinguish its appropriate hand, let the base be directed backwards and the pisiform facet upwards; the concave articular surface will point to the hand to which the bone belongs.

Articulations.—With three bones, and with the triangular fibrocartilage. By the base, with the semilunare; by the concave surface, with the unciforme; by the circular facet, with the pisiforme; and by the superior angle of the rough surface, with the fibro-cartilage.

The pisiform bone may be recognized by its small size, and by possessing a singular articular facet. If it be examined carefully, it will be observed to present four sides and two extremities; one side is articular, the smooth facet approaching nearer to the superior than the inferior extremity. The side opposite to this is rounded, and the remaining sides are, one slightly concave, the other slightly convex.

If the bone be held so that the articular facet shall look downwards, and the extremity which overhangs the articular facet forwards, the concave side will point to the hand to which it belongs.

Articulations.—With the cuneiform bone only.

Attachments.—To two muscles, the flexor carpi ulnaris, and abductor minimi digitii; and to the anterior annular ligament.

The trapezium (os multangulum majus) is too irregular in form to be compared to any known object; it may be distinguished by a deep groove, for the tendon of the flexor carpi radialis muscle. It is somewhat compressed, and may be divided into two surfaces which are smooth and articular, and three rough borders. One of the articular surfaces is oval, concave in one direction, and convex in the other (saddle-seat shaped); the other is marked into three facets. One of the borders presents the groove for the tendon of the flexor carpi radialis, which is surmounted by a prominent tubercle for the attachment of the annular ligament; the other two borders are rough and form the outer side of the carpus. The grooved border is narrow at
one extremity and broad at the other, where it presents the groove and tubercle.

If the bone be held so that the grooved border look upwards while the apex of this border be directed forwards, and the base with the tubercle backwards, the concavo-convex surface will point to the hand to which the bone belongs.

Articulations.—With four bones; by the concavo-convex surface, with the metacarpal bone of the thumb; and by the three facets of the other articular surface, with the scaphoid, trapezoid, and second metacarpal bone.

Attachments.—To two muscles, abductor pollicis and flexor ossis metacarpi; and by the tubercle, to the annular ligament.

The TRAPEZOIDES (os multangulum minus) is a small, oblong, and quadrilateral bone, bent near its middle upon itself (bean-shaped). It presents four articular surfaces and two extremities. One of the surfaces is concavo-convex, i.e. concave in one direction, and convex in the other; another, contiguous to the preceding, is concave, so as to be almost angular in the middle, and is often marked by a small rough depression, for an interosseous ligament; the two remaining sides are flat, and present nothing remarkable. One of the two extremities is broad and of large size, the dorsal; the other, or palmar, is small and rough.

If the bone be held perpendicularly, so that the broad extremity be upwards, and the concavo-convex surface forwards, the angular concave surface will point to the hand to which the bone belongs.

Articulations.—With four bones; by the concavo-convex surface, with the second metacarpal bone; by the angular concave surface, with the os magnum; and by the other two surfaces, with the trapezium and scaphoid.

Attachments.—To the flexor brevis pollicis muscle.

The OS MAGNUM (capitatum) is the largest bone of the carpus, and is divisible into a body and head. The head is round for the greater part of its extent, but is flattened on one side. The body is irregularly quadrilateral, and presents four sides and a smooth extremity. Two of the sides are rough, the one being square and flat, the dorsal, the other rounded and prominent, the palmar; the other two sides are articular, the one being concave, the other convex. The extremity is a triangular articular surface, divided into three facets.

If the bone be held perpendicularly, so that the articular extremity look upwards and the broad dorsal surface backwards (towards the holder), the concave articular surface will point to the hand to which the bone belongs.

Articulations.—With seven bones; by the rounded head, with the cup formed by the scaphoid and semilunar bone; by the side of the convex surface, with the trapezoides; by the concave surface, with the unciniforme; and by the extremity, with the second, third, and fourth metacarpal bones.

Attachments.—To the flexor brevis pollicis muscle.
The **unciforme** is a triangular-shaped bone, remarkable for a long and curved process, which projects from its palmar aspect. It presents five surfaces;—three articular, and two free. One of the articular surfaces is divided by a slight ridge into two facets; the other two converge, and meet at a flattened angle.* One of the free surfaces, the dorsal, is rough and triangular; the other, palmar, also triangular, but somewhat smaller, gives origin to the unciform process.

If the bone be held perpendicularly, so that the articular surface with two facets look upwards, and the unciform process backwards (towards the holder), the concavity of the unciform process will point to the hand to which the bone belongs.

**Articulations.**—With *five* bones; by the two facets on its base, with the fourth and fifth metacarpal bones; by the two lateral articulating surfaces, with the magnum and cuneiforme; and by the flattened angle of its apex, with the semilunare.

**Attachments.**—To *two* muscles, adductor minimi digiti, and flexor brevis minimi digiti; and by the hook-shaped process to the annular ligament.

**Development.**—The bones of the carpus are each developed by a single centre; they are cartilaginous at birth. Ossification commences towards the end of the first year in the os magnum and unciforme; at the end of the third year in the cuneiforme; during the fifth year in the trapezium and semilunare; during the eighth, in the scaphoides; the ninth, in the trapezoides; and the twelfth in the pisiforme. The latter bone is the last in the skeleton to ossify; it is, in reality, a sesamoid bone of the tendon of the flexor carpi ulnaris.

* When the unciforme does not articulate with the semilunare, this angle is sharp.

† The hand viewed upon its anterior or palmar aspect. 1. The scaphoid bone. 2. The semilunare. 3. The cuneiforme. 4. The pisiforme. 5. The trapezium. 6. The groove in the trapezium that lodges the tendon of the flexor carpi radialis. 7. The trapezoides. 8. The os magnum. 9. The unciforme. 10, 10. The five metacarpal bones. 11, 11. The first row of phalanges. 12, 12. The second row. 13, 13. The third row, or ungual phalanges. 14. The first phalanx of the thumb. 15. The second and last phalanx of the thumb.
The number of articulations which each bone of the carpus presents with surrounding bones, may be expressed in figures, which will materially facilitate their recollection; the number for the first row is 5531, and for the second 4475.

**METACARPUS.**—The bones of the metacarpus are five in number. They are long bones, divisible into a head, shaft, and base.

The head is rounded at the extremity, and flattened at each side, for the insertion of strong ligaments; the shaft is prismatic, and marked deeply on each side, for the attachment of the interossei muscles; and the base is irregularly quadrilateral, and rough for the insertion of tendons and ligaments. The base presents three articular surfaces, one at each side, for the adjoining metacarpal bones; and one at the extremity for the carpus.

The metacarpal bone of the thumb is one-third shorter than the rest, flattened and broad on its dorsal aspect, and convex on its palmar side; the articular surface of the head is not so round as that of the other metacarpal bones; and the base has a single concav-convex surface, to articulate with the similar surface of the trapezium.

The metacarpal bones of the different fingers may be distinguished by certain obvious characters. The base of the metacarpal bone of the index finger is the largest of the four, and presents four articular surfaces. That of the middle finger may be distinguished by a rounded projecting process upon the radial side of its base, and two small circular facets upon its ulnar lateral surface. The base of the metacarpal bone of the ring-finger is small and square, and has two small circular facets to correspond with those of the middle metacarpal. The metacarpal bone of the little finger has only one lateral articular surface.

**Development.**—By two centres; one for the shaft, and one for the digital extremity, with the exception of the metacarpal bone of the thumb, the epiphysis of which, like that of the phalanges, occupies the carpal end of the bone. Ossification of the metacarpal bones commences in the embryo between the tenth and twelfth week, that is, soon after the bones of the fore-arm. The epiphyses make their appearance at the end of the second, or early in the third year, and the bones are completed at twenty.

**Articulations.**—The first with the trapezium; second, with the trapezium, trapezoides, and os magnum, and with the middle metacarpal bone; third, or middle, with the os magnum, and adjoining metacarpal bones; fourth, with the os magnum and unciforme, and with the adjoining metacarpal bones; and, fifth, with the unciforme, and with the metacarpal bone of the ring-finger.

The figures resulting from the number of articulations which each metacarpal bone possesses, taken from the radial to the ulnar side, are 13121.

**Attachment of Muscles.**—To the metacarpal bone of the thumb, *three*, the flexor ossis metacarpi, extensor ossis metacarpi, and first
dorsal interosseous; of the index finger, _five_, the extensor carpi radialis longior, flexor carpi radialis, first and second dorsal interosseous, and first palmar interosseous; of the middle finger, _four_, the extensor carpi radialis brevior, adductor pollicis, and second and third dorsal interosseous; of the ring-finger, _three_, the third and fourth dorsal interosseous, and second palmar; and of the little finger, _four_, extensor carpi ulnaris, adductors minimi digiti, fourth dorsal, and third palmar interosseous.

**Phalanges.**—The phalanges are the bones of the fingers; they are named from their arrangement in rows, and are fourteen in number, three to each finger, and two to the thumb. In conformation they are long bones, divisible into a shaft, and two extremities.

The _shaft_ is compressed from before backwards, convex on its posterior surface, and flat with raised edges in front. The metacarpal extremity, or _base_, in the first row is a simple concave articular surface, that in the other two rows a double concavity, separated by a slight ridge. The digital extremities of the first and second row present a pulley-like surface, concave in the middle, and convex on each side. The unequal extremity of the last phalanx is broad, rough, and expanded into a semilunar crest.

**Development.**—By _two_ centres; one for the shaft, and one for the base. Ossification commences first in the third phalanges, then in the first, and lastly in the second. The period of commencement corresponds with that of the metacarpal bones. The epiphyses of the first row appear during the third or fourth year, those of the second row during the fourth or fifth, and of the last during the sixth or seventh. The phalanges are perfected by the twentieth year.

**Articulations.**—The first row, with the metacarpal bones and second row of phalanges; the second row, with the first and third; and the third, with the second row.

**Attachment of Muscles.**—To the base of the _first phalanx_ of the thumb _four_ muscles, abductor pollicis, flexor brevis pollicis, adductor pollicis, and extensor primi internodii; and to the _second phalanx, two_, the flexor longus pollicis, and extensor secundi internodii. To the _first phalanx_ of the second, third, and fourth fingers, one dorsal and one palmar interosseous, and to the _first phalanx_ of the little finger, the abductor minimi digitii, flexor brevis minimi digitii, and one palmar interosseous. To the _second phalanges_, the flexor sublimis and extensor communis digitorum; and to the _last phalanges_, the flexor profundus and extensor communis digitorum.

**Pelvis and Lower Extremity.**

The bones of the pelvis are the two _ossa innominata_, the sacrum and the _coccyx_; and of the lower extremity, the _femur_, _patella_, _tibia_ and _fibula_, _tarsus_, _metatarsus_, and _phalanges_.

Os innominatum.—The os innominatum (os coxae) is an irregular flat bone, consisting in the young subject of three parts, which meet at the acetabulum. Hence it is usually described in the adult as divisible into three portions, ilium, ischium, and pubes. The ilium is the superior, broad, and expanded portion which forms the prominence of the hip, and articulates with the sacrum. The ischium is the inferior and strong part of the bone on which we sit. The os pubis is that portion which forms the front of the pelvis, and gives support to the external organs of generation.

The ilium may be described as divisible into an internal and external surface, a crest, and an anterior and posterior border.

The internal surface is bounded above by the crest, below by a prominent line, the linea ilio-pectinea, and before and behind by

the anterior and posterior borders; it is concave and smooth for the anterior two-thirds of its extent, and lodges the iliacus muscle. The posterior third is rough, for articulation with the sacrum, and is divided by a deep groove into two parts; an anterior or auricular portion, which is shaped like the pinna, and coated by cartilage in the fresh bone; and a posterior portion, which is very rough and uneven for the attachment of interosseous ligaments.

The external surface is uneven, partly convex, and partly concave; it is bounded above by the crest; below by a prominent arch, which forms the upper segment of the acetabulum; and before and behind, by the anterior and posterior borders. Crossing this surface in an arched direction, from the anterior extremity of the crest to a notch upon the lower part of the posterior border, is a groove, which lodges the gluteal vessels and nerve, the superior curved line; and below this, at a short distance, a rough ridge, the inferior curved line. The surface included between the superior curved line and the crest, gives origin to the gluteus medius muscle; that between the curved lines, to the gluteus minimus; and the rough interval between the inferior curved line and the arch of the acetabulum, to one head of the rectus. The posterior sixth of this surface is rough and raised, and gives origin to part of the gluteus maximus.

The crest of the ilium is arched and curved in its direction like the italic letter ψ, being bent inwards at its anterior termination, and outwards towards the posterior. It is broad for the attachment of three planes of muscles, which are connected with its external and internal borders or lips, and with the intermediate space.

The anterior border is marked by two projections, the anterior superior spinous process, which is the anterior termination of the crest, and the anterior inferior spinous process; the two processes being separated by a notch for the attachment of the sartorius muscle. This border terminates inferiorly in the lip of the acetabulum. The posterior border also presents two projections, the posterior superior and the posterior inferior spinous process, separated by a notch. Inferiorly this border is broad and arched, and forms the upper part of the great sacro-ischiatric notch.

The ischium is divisible into a thick and solid portion, the body, and into a thin and ascending part, the ramus; it may be considered also, for convenience of description, as presenting an external and internal surface, and three borders, posterior, inferior, and superior.

The external surface is rough and uneven, for the attachment of muscles; and broad and smooth above, where it enters into the formation of the acetabulum. Below the inferior lip of the acetabulum is a notch, which lodges the obturator externus muscle in its passage outwards to the trochanteric fossa of the femur. The internal surface is smooth, and somewhat encroached upon at its posterior border by the spine.

The posterior border of the ischium presents towards its middle a remarkable projection, the spine. Immediately above the spine is a
notch of large size, the *great sacro-ischiatic*, and below the spine the *lesser sacro-ischiatic notch*; the former being converted into a foramen by the lesser sacro-ischiatic ligament, gives passage to the pyriformis muscle, the gluteal vessels and nerve, pudic vessels and nerve, and ischiatic vessels and nerves; and the lesser, completed by the great sacro-ischiatic ligament, to the obturator internus muscle, and to the internal pudic vessels and nerve. The *inferior border* is thick and broad, and is called the *tuberosity*. The surface of the tuberosity is divided into three facets; one anterior, which is rough for the origin of the semi-membranosus; and two posterior, which are smooth, and separated by a slight ridge for the semi-tendinosus and biceps muscle. The inner margin of the tuberosity is bounded by a sharp ridge, which gives attachment to a prolongation of the great sacro-ischiatic ligament, and the outer margin by a prominent ridge, from which the quadratus femoris muscle arises. The *superior border* of the ischium is thin, and forms the lower circumference of the obturator foramen. The *ramus* of the ischium is continuous with the ramus of the pubis, and is slightly everted.

The *os pubis* is divided into a horizontal portion or *body* (horizontal ramus of Albinus), and a descending portion or *ramus*; it presents for examination an external and internal surface, a superior and inferior border, and symphysis.

The *external surface* is rough, for the attachment of muscles; and prominent at its outer extremity, where it forms part of the acetabulum. The *internal surface* is smooth, and enters into the formation of the cavity of the pelvis. The *superior border* is marked by a rough ridge, the *crest*; the inner termination of the crest is the *angle*; and the outer end, the *spine* or *tubercle*. Running outwards from the spine is a sharp ridge, the *pectineal line*, or linea iliopectinea, which marks the brim of the true pelvis. In front of the pectineal line is a smooth depression, which supports the femoral artery and vein, and a little more externally an elevated prominence, the *ilio-pectineal eminence*, which divides the surface for the femoral vessels, from another depression which overhangs the acetabulum, and lodges the psoas and iliacus muscles. The iliopectineal eminence moreover marks the junction of the pubes with the ilium. The *inferior border* is broad and deeply grooved, for the passage of the obturator vessels and nerve; and sharp upon the side of the ramus, to form part of the boundary of the obturator foramen. The *symphysis* is the inner extremity of the body of the bone; it is oval and rough, for the attachment of a ligamentous structure analogous to the intervertebral substance. The *ramus* of the pubes descends obliquely outwards, and is continuous with the ramus of the ischium. The inner border of the ramus forms with the corresponding bone the *arch of the pubes*, and at its inferior part is considerably everted, to afford attachment to the crus penis.

The *acetabulum* (cavitas cotyloidea) is a deep cup-shaped cavity, situated at the point of union between the ilium, ischium, and pubes;
a little less than two-fifths being formed by the ilium, a little more than two-fifths by the ischium, and the remaining fifth by the pubes. It is bounded by a deep rim or lip, which is broad and strong above, where most resistance is required, and marked in front by a deep notch, which is arched over in the fresh subject by a strong ligament, and transmits the nutrient vessels into the joint. At the bottom of the cup, and communicating with the notch, is a deep and circular pit (fundus acetabuli), which lodges a mass of fat, and gives attachment to the broad extremity of the ligamentum teres.

The obturator or thyroid foramen is a large oval interval between the ischium and pubes, bounded by a narrow rough margin, to which a ligamentous membrane is attached. The upper part of the foramen is increased in depth by the groove in the under surface of the os pubis, which lodges the obturator vessels and nerve.

Development.—By eight centres; three principal, one for the ilium, one for the ischium, and one for the pubes; and five secondary, one, the Y shaped piece for the interval between the primitive pieces in the acetabulum, one for the crest of the ilium, one (not constant) for the anterior and inferior spinous process of the ilium, one for the tuberosity of the ischium, and one (not constant) for the angle of the os pubis. Ossification commences in the primitive pieces, immediately after that in the vertebrae, firstly in the ilium, then in the ischium, and lastly in the pubes; the first ossific deposits being situated near to the future acetabulum. At birth, the acetabulum, the crest of the ilium, and the ramus of the pubes and ischium, are cartilaginous. The secondary centres appear at puberty, and the entire bone is not completed until the twenty-fifth year.

Articulations.—With three bones; sacrum, opposite innominatum, and femur.

Attachment of Muscles and Ligaments.—To thirty-five muscles; to the ilium, thirteen; by the outer lip of the crest, to the obliquus externus for two-thirds, and to the latissimus dorsi for one-third its length, and to the tensor vaginæ femoris by its anterior fourth; by the middle of the crest, to the internal oblique for three-fourths its length, by the remaining fourth to the erector spinae; by the internal lip, to the transversalis for three-fourths, and to the quadratus lumborum by the posterior part of its middle third. By the external surface, to the gluteus medius, minimus and maximus, and to one head of the rectus; by the internal surface, to the iliacus; and by the anterior border to the sartorius, and the other head of the rectus. To the ischium sixteen; by its external surface, the adductor magnus and obturator externus; by the internal surface, the obturator internus and levator ani; by the spine, the gemellus superior, levator ani, coccygeus, and lesser sacro-ischiatric ligament; by the tuberosity, the biceps, semitendinosus, semi-membranosus, gemellus inferior, quadratus femoris, erector penis, tranversus perinei, and great sacro-ischiatric ligament; and by the ramus, the gracilia, accelerator urinæ, and compressor urethrae. To the os pubis fifteen; by its upper border, the obliquus
PELVIS.

externus, obliquus internus, tranversalis, rectus, pyramidalis, pectineus, and psoas parvus; by its external surface, the adductor longus, adductor brevis and gracilis; by its internal surface, the levator ani, compressor urethrae, and obturator internus; and by the ramus, the adductor magnus, and accelerator urinae.

PELVIS.

The pelvis considered as a whole is divisible into a false and true pelvis; the former is the expanded portion, bounded on each side by

* A female pelvis. 1. The last lumbar vertebra. 2, 2. The intervertebral substance connecting the last lumbar vertebra with the fourth and sacrum. 3. The promontory of the sacrum. 4. The anterior surface of the sacrum, on which its transverse lines and foramina are seen. 5. The tip of the coccyx. 6, 6. The iliac fossæ, forming the lateral boundaries of the false pelvis. 7. The anterior superior spinous process of the ilium; left side. 8. The anterior inferior spinous process. 9. The acetabulum. a. The notch of the acetabulum. b. The body of the ischium. c. Its tuberosity. d. The spine of the ischium seen through the obturator foramen. e. The os pubis. f. The symphysis pubis. g. The arch of the pubes. h. The angle of the os pubis. i. The spine of the pubes; the prominent ridge between h and i is the crest of the pubes. k, k. The pectineal line of the pubes. l, l. The ilio-pectineal line; m, m, the prolongation of this line to the promontory of the sacrum. The line represented by h, l, l, k, k, k, k, and m, m, is the brim of the true pelvis. n. The ilio-pectineal eminence. o. The smooth surface which supports the femoral vessels. p, p. The great sacro-ischiatic notch.
the osa ili, and separated from the true pelvis by the linea iliopectinea. The true pelvis is all that portion which is situated beneath the linea ilio-pectinea. This line forms the margin or brim of the true pelvis, while the included area is called the inlet. The form of the inlet is heart-shaped, obtusely pointed in front at the symphysis pubis, expanded on each side, and encroached upon behind by a projection of the upper part of the sacrum, which is named the promontory. The cavity is somewhat encroached upon at each side by a smooth quadrangular plane of bone, corresponding with the internal surface of the acetabulum, and leading to the spine of the ischium. In front are two fosse around the obturator foramina, for lodging the obturator internus muscle, at each side. The inferior termination of the pelvis is very irregular, and is termed the outlet. It is bounded in front by the convergence of the rami of the ischium and pubes, which constitute the arch of the pubes; on each side by the tuberosity of the ischium, and by two irregular fissures formed by the greater and lesser sacro-ischiatic notches; and behind by the lateral borders of the sacrum, and by the coccyx.

The pelvis is placed obliquely with regard to the trunk of the body, so that the inner surface of the osa pubis is directed upwards, and would support the superincumbent weight of the viscera. The base of the sacrum rises nearly four inches above the level of the upper border of the symphysis pubis and the apex of the coccyx, somewhat more than half an inch above its lower border. If a line were carried through the central axis of the inlet, it would impinge by one extremity against the umbilicus, and by the other against the middle of the coccyx. The axis of the inlet is therefore directed downwards and backwards, while that of the outlet points downwards and forwards, and corresponds with a line drawn from the upper part of the sacrum, through the centre of the outlet. The axis of the cavity represents a curve, which corresponds very nearly with the curve of the sacrum, the extremities being indicated by the central points of the inlet and outlet. A knowledge of the direction of these axes is most important to the surgeon, as indicating the line in which instruments should be used in operations upon the viscera of the pelvis, and the direction of force in the removal of calculi from the bladder; and to the accoucheur, as explaining the course taken by the foetus during parturition.

There are certain striking differences between the male and female pelvis. In the male the bones are thicker, stronger, and more solid, and the cavity deeper and narrower. In the female the bones are lighter and more delicate, the iliac fossae are large, and the ilia expanded; the inlet, the outlet, and the cavity, are large, and the acetabula farther removed from each other; the cavity is shallow, the tuberosities widely separated, the obturator foramina triangular, and the span of the pubic arch greater. The precise diameter of the inlet and outlet, and the depth of the cavity, are important considerations to the accoucheur.

The diameters of the inlet or brim are three: 1. Antero-posterior,
sacro-pubic or conjugate; 2. tranverse; and 3. oblique. The ante- 
ero-posterior extends from the symphysis pubis to the middle of the 
promontory of the sacrum, and measures four inches. The tranverse 
extends from the middle of the brim on one side to the same point on the 
opposite, and measures five inches. The oblique extends from the 
sacro-ilial symphysis on one side, to the margin of the brim cor- 
responding with the acetabulum on the opposite, and also measures 
five inches.

The diameters of the outlet are two, antero-posterior, and transverse. 
The antero-posterior diameter extends from the lower part of the sym- 
physis pubis to the apex of the coccyx; and the tranverse, from the 
posterior part of one tuberosity to the same point on the opposite side; 
they both measure four inches. The cavity of the pelvis measures in 
depth four inches and a-half, posteriorly; three inches and a-half in the 
middle; and one and a half at the symphysis pubis.

FEMUR. The femur, the longest bone of the skeleton, is situated 
obliquely in the upper part of the lower limb, articulating by means 
of its head with the acetabulum, and inclining inwards as it descends, 
until it almost meets its fellow of the opposite side at the knee. In 
the female this obliquity is greater than in the male, in consequence 
of the greater breadth of the pelvis. The femur is divisible into a 
shaft, a superior, and an inferior extremity.

At the superior extremity is a rounded head, directed upwards and 
wards, and marked just below its centre by an oval depression for 
the ligamentum teres. The head is supported by a neck, which varies 
in length and obliquity according to sex and at various periods of life, 
being long and oblique in the adult male, shorter and more horizontal 
in the female and in old age. Externally to the neck is a large pro- 
cess, the trochanter major, which presents upon its anterior surface an 
oval facet, for the attachment of the tendon of the gluteus minimus 
muscle; and above, a double facet, for the insertion of the gluteus 
medius. On its posterior side is a vertical ridge, the linea quadrati 
for the attachment of the quadratus femoris muscle. Upon the inner 
side of the trochanter major is a deep pit, the trochanteric or digital 
fossa, in which are inserted the tendons of the pyriformis, gemellus 
superior and inferior, and obturator externus and internus muscles. 
Passing downwards from the trochanter major in front of the bone is 
an oblique ridge, which forms the inferior boundary of the neck, the 
anterior intertrochanteric line; and behind, another oblique ridge, the 
posterior intertrochanteric line, which terminates in a rounded tu- 
bercle upon the posterior and inner side of the bone, the trochanter 
minor.

The shaft of the femur is convex and rounded in front, and covered 
with muscles; and somewhat concave and raised into a rough and pro-
minent ridge behind, the linea aspera. The linea aspera near the 
upper extremity of the bone divides into three branches. The anterior 
branch is continued forwards in front of the lesser trochanter, and is
continuous with the anterior intertrochanteric line; the middle is continued directly upwards into the linea quadrati; and the posterior, broad and strongly marked, ascends to the base of the trochanter major. Towards the lower extremity of the bone the linea aspera divides into two ridges, which descend to the two condyles, and enclose a triangular space upon which rests the popliteal artery. The internal condyloid ridge is less marked than the external, and presents a broad and shallow groove, for the passage of the femoral artery. The nutritious foramen is situated in or near the linea aspera, at about one-third from its upper extremity, and is directed obliquely from below upwards.

The lower extremity of the femur is broad and porous, and divided by a smooth depression in front, and by a large fossa (fossa intercondyloidea) behind, into two condyles.

The external condyle is the broadest and most prominent, and the internal the narrowest and longest; the difference in length depending upon the obliquity of the femur, in consequence of the separation of the two bones at their upper extremities by the breadth of the pelvis. The external condyle is marked upon its outer side by a prominent tuberosity, which gives attachment to the external lateral ligament; and immediately beneath this is the fossa, which lodges the tendon of origin of the popliteus. By the internal surface it gives attachment to the anterior crucial ligament of the knee-joint; and by its upper and posterior part, to the external head of the gastrocnemius and to the plantaris. The internal condyle projects upon its inner side into a tuberosity, to which is attached the internal lateral ligament; above this tuberosity, at the extremity of the internal condyloid ridge, is a tubercle, for the insertion of the tendon of the adductor magnus; and beneath the tubercle, upon the upper surface of the condyle, a depression, from which the internal head of the gastrocnemius arises. The outer

side of the internal condyle is rough and concave, for the attachment of the posterior crucial ligament.

**Development.**—By five centres; one for the shaft, one for each extremity, and one for each trochanter. The femur is the first of the long bones to shew signs of ossification. In it, ossific matter is found immediately after the maxillae before the termination of the second month of embryonic life. The secondary deposits take place in the following order, in the condyloid extremity during the last month of foetal life; in the head towards the end of the first year; in the greater trochanter between the third and the fourth year; in the lesser trochanter between the thirteenth and fourteenth. The epiphyses and apophyses are joined to the diaphysis in the reverse order of their appearance, the junction commencing after puberty and not being completed for the condyloid epiphysis until after the twentieth year.

**Articulations.**—With three bones; with the os innominatum, tibia, and patella.

**Attachment of Muscles.**—To twenty-three; by the greater trochanter, to the gluteus medius and minimus, pyriformis, gemellus superior, obturator internus, gemellus inferior, obturator externus, and quadratus femoris; by the lesser trochanter, to the common tendon of the psoas and iliacus. By the linea aspera, its outer lip, to the vastus externus, gluteus maximus, and short head of the biceps; by its inner lip, to the vastus internus, pectineus, adductor brevis, and adductor longus; by its middle to the adductor magnus; by the anterior part of the bone, to the cruræus and subcruræus; by its condyles, to the gastrocnemius, plantaris, and popliteus.

* A diagram of the posterior aspect of the right femur, shewing the lines of attachment of the muscles. The muscles attached to the inner lip are,—p, the pectineus; ab, the adductor brevis; and al, the adductor longus. The middle portion is occupied for its whole extent by am, the adductor magnus; and is continuous superiorly with qf, the linea quadrati, into which the quadratus femoris is inserted. The outer lip is occupied by gm, the gluteus maximus; and b, the short head of the biceps.

† Cruveilheir remarks that this centre is so constant in the last fortnight of foetal life, that it may be regarded as an important proof of the foetus having reached its full term.
**PATELLA.**—The patella is a sesamoid bone, developed in the tendon of the quadriceps extensor muscle, and usually described as a bone of the lower extremity. It is heart-shaped in figure, the broad side being directed upwards and the apex downwards, the external surface convex, and the internal divided by a ridge into two smooth surfaces, to articulate with condyles of the femur. The external articular surface corresponding with the external condyle is the larger of the two, and serves to indicate the leg to which the bone belongs.

*Development.*—By a single centre, at about the middle of the third year.

*Articulations.*—With the two condyles of the femur.

*Attachment of Muscles.*—To four; the rectus, crurceus, vastus internus and vastus externus, and to the ligamentum patellae.

**TIBIA.**—The tibia is the inner and larger bone of the leg; it is prismoid in form, and divisible into a shaft, an upper and lower extremity.

The *upper extremity*, or head, is large, and expanded on each side into two *tuberosities*. Upon their upper surface the tuberosities are smooth, to articulate with the condyles of the femur; the internal articular surface being oval and oblong, to correspond with the internal condyle; and the external broad and nearly circular. Between the two articular surfaces is a *spinous process*; and in front and behind the spinous process a rough depression, giving attachment to the anterior and posterior crucial ligaments. Between the two tuberosities on the front aspect of the bone is a prominent elevation, the *tubercle*, for the insertion of the ligamentum patellæ, and immediately above the tubercle a smooth facet, corresponding with a bursa. Upon the outer side of the external tuberosity is an articular surface, for the

* The tibia and fibula of the right leg, articulated and seen from the front. 1. The shaft of the tibia. 2. The inner tuberosity. 3. The outer tuberosity. 4. The spinous process. 5. The tubercle. 6. The internal or subcutaneous surface of the shaft. 7. The lower extremity of the tibia. 8. The internal malleolus. 9. The shaft of the fibula. 10. Its upper extremity. 11. Its lower extremity, the external malleolus. The sharp border between 1 and 6 is the crest of the tibia.
head of the fibula; and upon the posterior part of the internal tube-
rosity a depression, for the insertion of the tendon of the semimem-
branosus muscle.

The shaft of the tibia presents three surfaces; internal, which is
subcutaneous and superficial; external, which is concave and marked
by a sharp ridge, for the insertion of the interosseous membrane; and
posterior, grooved, for the attachment of muscles. Near the upper
extremity of the posterior surface is an oblique ridge, the popliteal line,
for the attachment of the fascia of the popliteus muscle; and imme-
diately below the oblique line, the nutritious canal, which is directed
downwards.

The inferior extremity of the bone is somewhat quadrilateral, and
prolonged on its inner side into a large process, the internal malleolus.
Behind the internal malleolus, is a broad and shallow groove, for lodging
the tendons of the tibialis posticus and flexor longus digitorum; and
farther outwards another groove, for the tendon of the flexor longus
pollicis. Upon the outer side the surface is concave and triangular,
rough above, for the attachment of the interosseous ligament; and
smooth below, to articulate with the fibula. Upon the extremity of
the bone is a triangular smooth surface, for articulating with the
astragalus.

Development.—By three centres; one for the shaft, and one for
each extremity. Ossification commences in the tibia, immediately
after the femur; the centre for the head of the bone appears soon
after birth, and that for the lower extremity during the second year;
the latter is the first to join the diaphysis. The bone is not complete
until near the twenty-fifth year. Two occasional centres have some-
times been found in the tibia, one in the tubercle, the other in the in-
ternal malleolus.

Articulations.—With three bones; femur, fibula, and astragalus.

Attachment of Muscles.—To ten; by the internal tuberosity, to the
sartorius, gracilis, semitendinosus, and semimembranosus; by the ex-
ternal tuberosity, to the tibialis anticus and extensor longus digitorum;
by the tubercle, to the ligamentum patellae; by the external surface of
the shaft, to the tibialis anticus; and by the posterior surface, to the
popliteus, soleus, flexor longus digitorum, and tibialis posticus.

FIBULA.—The fibula (πρόχωρη, a brooch, from its resemblance, in
conjunction with the tibia, to the pin of an ancient brooch) is the
outer and smaller bone of the leg; it is long and slender in figure,
prismoid in shape, and, like other long bones, is divisible into a shaft
and two extremities.

The superior extremity or head is thick and large, and depressed
upon the upper part by a concave surface, which articulates with the
external tuberosity of the tibia. Externally to this surface is a thick
and rough prominence, for the attachment of the external lateral liga-
ment of the knee-joint, terminated behind by a styloid process, for
the insertion of the tendon of the biceps.
The lower extremity is flattened from without inwards, and prolonged downwards beyond the articular surface of the tibia, forming the external malleolus. Its external side presents a rough and triangular surface, which is subcutaneous. Upon the internal surface is a smooth triangular facet, to articulate with the astragalus; and a rough depression, for the attachment of the interosseous ligament. The anterior border is thin and sharp; and the posterior, broad and grooved, for the tendons of the peronei muscles.

To place the bone in its proper position, and ascertain to which leg it belongs, let the inferior or flattened extremity be directed downwards, and the narrow border of the malleolus forwards; the triangular subcutaneous surface will then point to the side corresponding with the limb of which the bone should form a part.

The shaft of the fibula is prismoid, and presents three surfaces; external, internal, and posterior; and three borders. The external surface is the broadest of the three; it commences upon the anterior part of the bone above, and curves around it so as to terminate upon its posterior side below. This surface is completely occupied by the two peronei muscles. The internal surface commences on the side of the superior articular surface, and terminates below, by narrowing to a ridge, which is continuous with the anterior border of the malleolus. It is marked along its middle by the interosseous ridge, which is lost above and below in the inner border of the bone. The posterior surface is twisted like the external, it commences above on the posterior side of the bone, and terminates below on its internal side; at about the middle of this surface is the nutritious foramen, which is directed downwards.

The internal border commences superiorly in common with the interosseous ridge, and bifurcates inferiorly into two lines,
which bound the triangular subcutaneous surface of the external malleolus. The external border begins at the base of the styloid process upon the head of the fibula, and winds around the bone, following the direction of the corresponding surface. The posterior border is sharp and prominent, and is lost inferiorly in the interosseous ridge. 

Development.—By three centres; one for the shaft, and one for each extremity. Ossification commences in the shaft soon after its appearance in the tibia; at birth the extremities are cartilaginous, an ossific deposit taking place in the inferior epiphysis during the second year, and in the superior during the fourth or fifth. The inferior epiphysis is the first to become united with the diaphysis, but the bone is not completed until nearly the twenty-fifth year.

Articulations.—With the tibia and astragalus.

Attachment of Muscles.—To nine; by the head, to the tendon of the biceps and soleus; by the shaft, its external surface, to the peroneus longus and brevis; internal surface, to the extensor longus digitorum, extensor proprius pollicis, peroneus tertius, and tibialis posticus; by the posterior surface, to the popliteus and flexor longus pollicis.

Tarsus.—The bones of the tarsus are seven in number; viz. the astragalus, calcaneus, scaphoid, internal middle, and external cuneiform and cuboid.

The Astragalus (os tali) may be recognised by its rounded head, a broad articular facet upon its convex surface, and two articular facets, separated by a deep groove, upon its concave surface.

The bone is divisible into a superior and inferior surface, an external and internal border, and an anterior and posterior extremity. The superior surface is convex, and presents a large quadrilateral and smooth facet somewhat broader in front than behind, to articulate with the tibia. The inferior surface is concave, and divided by a deep and rough groove (sulcus tali), which lodges a strong interosseous ligament, into two facets, the posterior large and quadrangular, and the anterior smaller and elliptic, which articulate with the os calcis. The internal border is flat and irregular, and marked by a pyriform articular surface, for the inner malleolus. The external presents a large triangular articular facet, for the external malleolus, and is rough and concave in front. The anterior extremity presents a rounded head, surrounded by

The surface of the shaft upon which the flexor longus digitorum muscle rests.
8. The broad groove on the back part of the inner malleolus, for the tendons of the flexor longus digitorum and tibialis posticus. 9. The groove for the tendon of the flexor longus pollicis. 10. The shaft of the fibula. The flexor longus pollicis muscle lies upon this surface of the bone; its superior limit being marked by the oblique line immediately above the number. 11. The styloid process on the head of the fibula for the attachment of the tendon of the biceps muscle. 12. The subcutaneous surface of the lower part of the shaft of the fibula. 13. The external malleolus formed by the lower extremity of the fibula. 14. The groove upon the posterior part of the external malleolus for the tendons of the peronei muscles.
a constriction somewhat resembling a neck; and the posterior extremity is narrow, and marked by a deep groove, for the tendon of the flexor longus pollicis.

Hold the astragalus with the broad articular surface upwards, and the rounded head forwards; the triangular lateral articular surface will point to the side to which the bone belongs.

Articulations.—With four bones; tibia, fibula, calcaneus, and scaphoid.

The **Calcaneus** (os calcis) may be known by its large size and oblong figure, by the large and irregular portion which forms the heel, and by two articular surfaces, separated by a broad groove upon its upper side.

The calcaneus is divisible into four surfaces, superior, inferior, external, and internal; and two extremities, anterior and posterior. The **superior surface** is convex behind and irregularly concave in front, where it presents two, and sometimes three articular facets, divided by a broad and shallow groove (sulcus calcanei), for the interosseous ligament. The **inferior surface** is convex and rough, and bounded posteriorly by the two inferior tuberosities, of which the internal is broad and large, and the external smaller and prominent. The **external surface** is convex and subcutaneous, and marked towards its anterior third by two grooves, often separated by a tubercle, for the tendons of the peroneus longus and brevis. The **internal surface** is concave and grooved, for the tendons and vessels which pass into the sole of the foot. At the anterior extremity of this surface is a projecting pro-

---

cess (sustentaculum tali,) which supports the anterior articulating surface of the astragalus, and serves as a pulley to the tendon of the flexor longus digitorum. Upon the anterior extremity is a flat articular surface, surmounted by a rough projection, which affords one of the guides to the surgeon in the performance of Chopart's operation. The posterior extremity is prominent and convex, and constitutes the posterior tuberosity; it is smooth for the upper half of its extent, where it corresponds with a bursa; and rough below, for the insertion of the tendon Achillis; the lower part of this surface is bounded by the two inferior tuberosities.

Articulations.—With two bones; the astragalus and cuboid. In their articulated state a large oblique canal is situated between the astragalus and calcaneus, being formed by the apposition of the two grooves sulcus tali and calcanei. This groove is called the sinus tarsi, and serves to lodge a strong intersosseous ligament which binds the two bones together.

Attachment of Muscles.—To nine; by the posterior tuberosity, to the tendon Achillis and plantaris; by the inferior tuberosities and under surface, to the abductor pollicis, abductor minimi digiti, flexor brevis digitorum, flexor accessorius, and to the plantar fascia; and by the external surface, to the extensor brevis digitorum.

The Scaphoid bone may be distinguished by its boat-like figure, concave on one side, and convex with three facets upon the other. It presents for examination an anterior and posterior surface, a superior and inferior border, and two extremities, one broad, the other pointed and thick. The anterior surface is convex, and divided into three facets, to articulate with the three cuneiform bones; and the posterior concave, to articulate with the rounded head of the astragalus. The superior border is convex and rough, and the inferior somewhat concave and irregular. The external extremity is broad and rough, and the internal pointed and prominent, so as to form a tuberosity. The external extremity sometimes presents a facet of articulation with the cuboid.

If the bone be held so that the convex surface with three facets look forwards, and the convex border upwards, the broad extremity will point to the side corresponding with the foot to which the bone belongs.

Articulations.—With four bones; astragalus and three cuneiform bones, sometimes also with the cuboid.

Attachment of Muscles.—To the tendon of the tibialis posticus.

The Internal Cuneiform may be known by its irregular wedge-shape, and by being larger than the two other bones bearing the same name. It presents for examination a convex and a concave surface, a long and a short articular border, and a small and a large extremity.

Place the bone so that the small extremity may look upwards and
the long articular border forwards, the concave surface will point to
the side corresponding with the foot to which it belongs.

The convex surface is internal and free, and assists in forming the
inner border of the foot, the concave is external, and in apposition
with the middle cuneiform and second metatarsal bone; the long
border articulates with the metatarsal bone of the great toe, and the
short border with the scaphoid bone. The small extremity (edge) is
sharp, and the larger extremity (base) rounded into a broad tube-
rosity.

Articulations.—With four bones; scaphoid, middle cuneiform, and
first two metatarsal bones.

Attachment of Muscles.—To the tibialis anticus, and posticus.

The Middle Cuneiform is the smallest of the three; it is wedge-
shaped, the broad extremity being placed upwards, and the sharp end
downwards in the foot. It presents for examination four articular
surfaces and two extremities. The anterior and posterior surfaces
have nothing worthy of remark. One of the lateral surfaces has a
long articular facet, extending its whole length, for the internal cunei-
form; the other has only a partial articular facet for the external
cuneiform bone.

If the bone be held so that the square extremity look upwards,
the broadest side of the square being towards the holder, the small
and partial articular surface will point to the side to which the bone
belongs.

Articulations.—With four bones; scaphoid, internal and external
cuneiform, and second metatarsal bone.

Attachment of Muscles.—To the flexor brevis pollicis.

The External Cuneiform is intermediate in size between the
two preceding, and placed, like the middle, with the broad end up-
wards and the sharp extremity downwards. It presents for examina-
tion five surfaces, and a superior and inferior extremity. The upper
extremity is flat, of an oblong square form, and bevelled posteriorly, at
the expense of the outer surface, into a sharp edge.

If the bone be held so that the square extremity look upwards and
the sharp border backwards, the bevelled surface will point to the side
corresponding with the foot to which the bone belongs.

Articulations.—With six bones; scaphoid, middle cuneiform, cuboid,
and second, third, and fourth metatarsal bones.

Attachment of Muscles.—To the flexor brevis pollicis.

The Cuboid bone is irregularly cuboid in form, and marked upon
its under surface by a deep groove, for the tendon of the peroneus
longus muscle. It presents for examination six surfaces, three articular
and three non-articular. The non-articular surfaces are the superior,
which is slightly convex, and assists in forming the dorsum of the
foot; the *inferior*, marked by a prominent ridge, the *tuberosity*, and a deep groove for the tendon of the peroneus longus; and an *external*, the smallest of the whole, and deeply notched by the commencement of the peroneal groove. The *articular surfaces* are, the *posterior*, which is of large size, and concavo-convex, to articulate with the os calcis; *anterior*, of smaller size, divided by a slight ridge into two facets, for the fourth and fifth metatarsal bones; and *internal*, a small oval articular facet, upon a large and quadrangular surface, for the external cuneiform bone.

If the bone be held so that the plantar surface, with the peroneal groove, look downwards, and the largest articular surface backwards, the small non-articular surface, marked by the deep notch, will point to the side corresponding with the foot to which the bone belongs.

*Articulations.*—With *four* bones; calcaneus, external cuneiform, and fourth and fifth metatarsal bones, sometimes also with the scaphoid.

*Attachment of Muscles.*—To *three*; the flexor brevis pollicis, adductor pollicis, and flexor brevis minimi digitii.

Upon a consideration of the articulations of the tarsus it will be observed, that each bone articulates with four adjoining bones, with the exception of the calcaneus, which articulates with two, and the external cuneiform with six.

*Development.*—By a single centre for each bone, with the exception of the os calcis, which has an epiphysis for its posterior tuberosity. The centres appear in the following order; calcanean, sixth month; astragalus, seventh month; cuboid, tenth month; external cuneiform, during the first year; internal cuneiform, during the third year; middle cuneiform and scaphoid, during the fourth year. The epiphysis of the calcaneus appears at the ninth year and is united with the diaphysis at about the fifteenth.

The *Metatarsal bones*, five in number, are long bones, and divisible therefore into a shaft and two extremities. The shaft is prismatic, and compressed from side to side; the posterior extremity, or base, is square-shaped, to articulate with the tarsal bones, and with each other; and the anterior extremity presents a rounded head, circumscribed by a neck, to articulate with the first row of phalanges.

*Peculiar Metatarsal bones.*—The *first* is shorter and larger than the rest, and forms part of the inner border of the foot; its posterior extremity presents only one lateral articular surface, and an oval rough prominence beneath, for the insertion of the tendon of the peroneus longus. The anterior extremity has, upon its plantar surface, two grooved facets, for sesamoid bones.

The *second* is the longest and largest of the remaining metatarsal bones; it presents at its base three articular facets, for the three cuneiform bones; a large oval facet, but often no articular surface, on its inner side, to articulate with the metatarsal bone of the great toe, and two externally, for the third metatarsal bone.

The *third* may be known by two facets upon the outer side of its
base, corresponding with the second, and may be distinguished by its smaller size.

The fourth may be distinguished by its smaller size, and by having a single articular surface on each side of the base.

The fifth is recognised by its broad base, and by its large tuberosity in place of an articular surface upon its outer side.

**Development.**—Each bone by two centres; one for the body and one for the digital extremity in the four outer metatarsal bones; and one for the body, the other for the base in the metatarsal bone of the great toe. Ossific deposition appears in these bones at the same time with the vertebrae; the epiphyses, commencing with the great toe and proceeding to the fifth, appear towards the close of the second year, consolidation being effected at eighteen.

**Articulations.**—With the tarsal bones by one extremity, and with the first row of phalanges by the other. The number of tarsal bones with which each metatarsal articulates from within outwards, is the same as between the metacarpus and carpus, one for the first, three for the second, one for the third, two for the fourth, and one for the fifth, forming the cipher 13121.

**Attachment of Muscles.**—To fourteen; to the first, the peroneus longus and first dorsal interosseous muscle; to the second, two dorsal interossei and transversus pedis; to the third, two dorsal and one plantar interosseous, adductor pollicis and transversus pedis; to the fourth, two dorsal and one plantar interosseous, adductor pollicis and

The internal cuneiform bone; its broad extremity. 8. The middle cuneiform bone. 9. The external cuneiform bone. 10, 11. The cuboid bone. 11. Refers to the groove for the tendon of the peroneus longus: the prominence between this groove and figure 10 is the tuberosity. 12, 12. The metatarsal bones. 13, 13. The first phalanges. 14, 14. The second phalanges of the four lesser toes. 15, 15. The third, or ungual phalanges of the four lesser toes. 16. The last phalanx of the great toe.
transversus pedis; to the fifth, one dorsal and one plantar interrosseous peroneus brevis, peroneus tertius, abductor minimi digiti, flexor brevis minimi digiti, and transversus pedis.

**Phalanges.**—There are two phalanges in the great toe, and three in the other toes, as in the hand. They are long bones, divisible into a central portion and extremities.

The phalanges of the first row are convex above, concave upon the under surface, and compressed from side to side. The posterior extremity has a single concave articular surface, for the head of the metatarsal bone; and the anterior extremity, a pulley-like surface, for the second phalanx.

The *second phalanges* are short and diminutive, but somewhat broader than those of the first row.

The *third, or ungual phalanges*, including the second phalanx of the great toe, are flattened from above downwards, spread out laterally at the base, to articulate with the second row, and at the opposite extremity, to support the nail and the rounded extremity of the toe.

**Development.**—By two centres; one for the body and one for the metacarpal extremity. Ossification commences in these bones after that in the metatarsus, appearing first in the last phalanges, then in the first, and last of all in the middle row. The bones are completed at eighteen.

**Articulations.**—The first row with the metatarsal bones and second phalanges; the second, of the great toe with the first phalanx, and of the other toes with the first and third phalanges; and the third, with the second row.

**Attachment of Muscles.**—To twenty-three; to the *first phalanges; great toe*, the innermost tendon of the extensor brevis digitorum, abductor pollicis, adductor pollicis, flexor brevis pollicis, and transversus pedis; *second toe*, first dorsal and first palmar interrosseous and lumbricalis; *third toe*, second dorsal and second palmar interrosseous and lumbricalis; *fourth toe*, third dorsal and third palmar interrosseous and lumbricalis; *fifth toe*, fourth dorsal interrosseous, abductor minimi digiti, flexor brevis minimi digiti and lumbricalis. *Second phalanges; great toe*, extensor longus pollicis, and flexor longus pollicis; *other toes*, one slip of the common tendon of the extensor longus and extensor brevis digitorum, and flexor brevis digitorum. *Third phalanges; two slips of the common tendon of the extensor longus and extensor brevis digitorum, and the flexor longus digitorum.*

**Sesamoid Bones.**—These are small osseous masses, developed in those tendons which exert a certain degree of force upon the surface over which they glide, or where, by continued pressure and friction, the tendon would become a source of irritation to neighbouring parts, as to joints. The best example of a sesamoid bone is the patella, developed in the common tendon of the quadriceps extensor, and resting upon the front of the knee-joint. Besides the patella, there are four
pairs of sesamoid bones included in the number of pieces which compose the skeleton, two upon the metacarpo-phalangeal articulation of each thumb, and existing in the tendons of insertion of the flexor brevis pollicis, and two upon the corresponding joint in the foot, in the tendons of the muscles inserted into the base of the first phalanx. In addition to these there is often a sesamoid bone upon the metacarpo-phalangeal joint of the little finger; and upon the corresponding joint in the foot, in the tendons inserted into the base of the first phalanx; there is one also in the tendon of the peroneus longus muscle, where it glides through the groove in the cuboid bone; sometimes in the tendons, as they wind around the inner and outer malleolus; in the psoas and iliacus, where they glide over the body of the os pubis; and in the external head of the gastrocnemius.

The bones of the tympanum, as they belong to the apparatus of hearing, will be described with the anatomy of the ear.
CHAPTER II.

ON THE LIGAMENTS.

The bones are variously connected with each other in the construction of the skeleton, and the connection between any two bones constitutes a joint or articulation. If the joint be immovable, the surfaces of the bones are applied in direct contact; but if motion be intended, the opposing surfaces are expanded, and coated by an elastic substance, named cartilage; a fluid secreted by a membrane closed on all sides lubricates their surface, and they are firmly held together by means of short bands of glistening fibres, which are called ligaments (ligare, to bind). The study of the ligaments is named syndesmology (συν together, δέσμος bond), which, with the anatomy of the articulations, forms the subject of the present chapter.

The forms of articulation met with in the human frame may be considered under three classes:—Synarthrosis, Amphi-arthrosis, and Diarthrosis.

Synarthrosis (σύν, συνεχομεν articulation) is expressive of the fixed form of joint in which the bones are immovably connected with each other. The kinds of synarthrosis are four in number. 1. Sutura. 2. Harmonia. 3. Schindylesis. 4. Gomphosis. The characters of the three first have been sufficiently explained in the preceding chapter, p. 52. It is here only necessary to state that, in the construction of sutures, the substance of the bones is not in immediate contact, but is separated by a layer of membrane which is continuous externally with the pericranium and internally with the dura mater. It is the latter connection which gives rise to the great difficulty sometimes experienced in tearing the calvarium from the dura mater. Cruveilhier describes this interposed membrane as the sutural cartilage; I never saw any structure in the sutures which could be regarded as cartilage, and the history of the formation of the cranial bones would seem to point to a different explanation. The fourth, Gomphosis (γόμφος, a nail), is expressive of the insertion of one bone into another, in the same manner that a nail is fixed into a board; this is illustrated in the articulation of the teeth with the alveoli of the maxillary bones.

Amphi-arthrosis (ἀμφί both, ἀνεκθωμεν) is a joint intermediate in aptitude for motion between the immovable synarthrosis and the movable diarthrosis. It is constituted by the approximation of surfaces partly coated with cartilage lined by synovial membrane, and
ARTICULATIONS.

partly connected by interosseous ligaments, or by the intervention of an elastic fibro-cartilage which adheres to the ends of both bones. Examples of this articulation are seen in the union between the bodies of the vertebrae, of the sacrum with the coccyx, of the pieces of the sternum, the sacro-iliac and pubic symphyses (συν, φισν to grow together), and according to some, of the necks of the ribs, with the transverse processes.

Diarthrosis (δια through, ἄθεσε is) is the movable articulation, which constitutes by far the greater number of the joints of the body. The degree of motion in this class has given rise to a subdivision into three genera, Arthrodia, Ginglvmus, and Enarthrosis.

Arthrodia is the movable joint in which the extent of motion is slight and limited, as in the articulation of the clavicle, of the ribs, articular processes of the vertebrae, axis with the atlas, radius with the ulna, fibula with the tibia, carpal and metacarpal, tarsal and metatarsal bones.

Ginglvmus (γυγελμος, a hinge), or hinge-joint, is the movement of bones upon each other in two directions only, viz. forwards and backwards; but the degree of motion may be very considerable. The instances of this form of joint are numerous; they comprehend the elbow, wrist, metacarpo-phalangeal and phalangeal joints in the upper extremity; and the knee, ankle, metatarso-phalangeal and phalangeal joints in the lower extremity. The lower jaw may also be admitted into this category, as partaking more of the character of the hinge-joint than of the less movable arthrodia.

The form of the ginglvmoid joint is somewhat quadrilateral, and each of its four sides is provided with a ligament, which is named from its position, anterior, posterior, internal, or external lateral. The lateral ligaments are thick and strong, and are the chief bond of union between the bones. The anterior and posterior are thin and loose in order to permit the required extent of movement.

Enarthrosis (ἐν in, ἄθεσε is) is the most extensive in its range of motion of all the movable joints. From the manner of connection and form of the bones in this articulation, it is called the ball and socket-joint. There are two instances in the body, viz. the hip and the shoulder.

I have been in the habit of adding to the preceding the carpo-meta-carpal articulation of the thumb, although not strictly a ball-and-socket joint, from the great extent of motion which it enjoys, and from the nature of the ligament connecting the bones. As far as the articular surfaces are concerned, it is rather a double than a single ball-and-socket, and the whole of these considerations remove it from the simple arthrodia and ginglvmoid groups.

The ball and socket-joint has a circular form; and, in place of the four distinct ligaments of the ginglvmus, is enclosed in a bag of ligamentous membrane, called a capsular ligament.

The kinds of articulation may probably be conveyed in a more satisfactory manner in the tabular form, thus:
Examples.

Synarthrosis

Sutura . . . bones of the skull.
Harmonia . . . superior maxillary bones.
Schindylesis . . . vomer with rostrum.
Gomphosis . . . teeth with alveoli.

Diarthrosis.

Arthrodia . . . carpal and tarsal bones.
Ginglymus . . . elbow, wrist, knee, ankle.
Enarthrosis . . . hip, shoulder.

The motions permitted in joints may be referred to four heads, viz.

1. Gliding is the simple movement of one articular surface upon another, and exists to a greater or less extent in all the joints. In the least movable joints as in the carpus and tarsus, this is the only motion which is permitted.

2. Angular movement may be performed in four different directions, either forwards and backwards, as in flexion and extension; or inwards and outwards, constituting adduction and abduction. Flexion and extension are illustrated in the ginglymoid joint, and exist in a large proportion of the joints of the body. Adduction and abduction conjointed with flexion and extension, are met with complete, only in the most movable joints, as in the shoulder, the hip, and the thumb. In the wrist and in the ankle adduction and abduction are only partial.

3. Circumduction is most strikingly exhibited in the shoulder and hip joints; it consists in the slight degree of motion which takes place in the head of a bone against its articular cavity, while the extremitv of the limb is made to describe a large circle upon a plane surface. It is also seen, but in a less degree, in the carpo-metacarpal articulation of the thumb, metacarpo-phalangeal articulations of the fingers and toes, and in the elbow when that joint is flexed and the end of the humerus fixed.

4. Rotation is the movement of a bone upon its own axis, and is illustrated in the hip and shoulder, or better in the rotation of the cup of the radius, against the eminentia capitata of the humerus. Rotation is also observed in the movements of the atlas upon the axis, in which the odontoid process serves as a pivot around which the atlas turns.

The structures entering into the composition of a joint are bone, cartilage, fibrous tissue, adipose tissue, and synovial membrane. Cartilage forms a thin coating to the articular extremities of bones, sometimes presenting a smooth surface which moves on a corresponding smooth surface of the articulating bone; sometimes forming a plate smooth on both surfaces and interposed between the cartilaginous ends of two bones, interarticular; and sometimes acting as the connecting medium between bones without any free surface, interosseous. Fibrous tissue enters into the construction of joints under the form of ligament, in one situation constituting bands of various breadth and thickness,
in another a layer which extends completely around the joint and is then called a capsular ligament. All the ligaments of joints are composed of that variety of fibrous tissue termed white fibrous tissue, but in some situations ligaments are found which consist of yellow fibrous tissue, for example, the ligamenta subflava of the arches of the vertebral column. Adipose tissue exists in variable quantity in relation with joints, where it performs, among other offices, that of a valve or spring, which occupies any vacant space that may be formed during the movements of the joint, and effectually prevents the occurrence of a vacuum in those cavities. This purpose of adipose tissue is exemplified in the cushion of fat at the bottom of the acetabulum and in the similar cushion behind the ligamentum patellæ. Synovial membrane constitutes the beautiful smooth and polished lining of a joint, and contains the fluid termed synovia by means of which the adapted surfaces are enabled to move upon each other with the perfect ease and freedom which are known to exist.

**Cartilage.**—In the structure of joints, cartilage serves the double purpose of a connecting and separating medium. In the former capacity possessing great strength, and in the latter smoothness and elasticity. In reference to its intimate structure it admits of classification into three kinds, true cartilage, reticular cartilage, and fibrous cartilage.

*True Cartilage* is composed of a semi-transparent homogeneous substance (hyaline or vitreous substance) containing a number of minute cells (cartilage corpuscles) dispersed at short intervals through its

*Fig. 47.*

* A portion of articular cartilage from the head of the fibula. The section is made vertically to the surface, and magnified 155 times. A. The appearance and arrangement of the cells near to the bone. The irregular line to the right is the boundary of the bone. B. A view of the same section, at about midway between the bone and the free surface. C. A portion near the synovial surface; the line to the left is that of the synovial boundary.
The cells are oval, oblong, or polyhedral in shape, and more or less flattened; their membranous envelope is blended with the intercellular substance, and they contain in their interior secondary cells, nuclei, nucleoli, oil globules, and more or less of granular matter. Cartilage cells have an average measurement of \( \frac{1}{1500} \) of an inch in their long diameter; they are sometimes isolated, sometimes grouped in pairs, and sometimes disposed in a linear group of three or four. They are larger near the bone than at the surface, and in the latter situation are long and slender in form, and arranged in rows having their long axis parallel with the plane of the surface. True cartilage is pearl-white or bluish and opaline in colour, and its intercellular substance is semitransparent and structureless. These characters, however, are changed when it exhibits a tendency to ossify. In the latter case the intercellular substance becomes fibrous and more or less opake, its colour is yellowish, and the cells are found to contain a greater number of oil-globules than in its natural state.

The true cartilages are, the articular, costal, ensiform, thyroid, cricoid, arytenoid, tracheal and bronchial, nasal, meatus auris, the pulley of the trochlearis muscle, and temporary cartilage or the cartilage of bone previously to ossification.*

Reticular cartilage is composed of cells \( \frac{1}{1500} \) of an inch in diameter

* Page 5.
† A portion of reticular cartilage. The section is taken from the pinna, and magnified 155 times.
separated from each other by an opaque, subfibrous, intercellular network, the breadth of the cells being considerably greater than that of the intercellular structure. The cells are parent cells, containing others of secondary formation, together with nuclei, nucleoli, granular matter, and oil-globules in greater number than those of true cartilage. The fibres are short, imperfect, loose in texture, and yellowish. The instances of reticular cartilage are, the pinna, epiglottis, and Eustachian tube.

*Fibrous cartilage* is composed of a network of white glistening fibres collected into fasciculi of various size, and containing in its meshes cells and a subfibrous tissue resembling that of reticular cartilage. The fibres of fibrous cartilage are identical with those of fibrous tissue, the cells are large (about \(\frac{1}{4}\) of an inch) as in reticular cartilage, and the areolae are variable in dimensions. It is this latter character that constitutes the difference between different fibrous cartilages, some being composed almost entirely of fibres with few and small interstices, as the interarticular cartilages, while others exhibit large spaces filled with an imperfect fibrous tissue and cells, as the intervertebral substance.

The fibrous cartilages admit of arrangement into four groups, namely, interarticular, stratiform, interosseus, and free. The instances of *interarticular fibrous cartilages* (menisci) are those of the lower jaw, sternal and acromial end of the clavicle, wrist, carpus, knee, to which may be added the fibrous cartilages of circumference, glenoid and cotyloid. The *stratiform fibrous cartilages* are such as form a thin coating to the grooves on bone through which tendons play. The *interosseous fibrous cartilages* are the intervertebral substance and symphysis pubis. The *free fibrous cartilages* are the tarsal cartilages of the eyelids.

* A portion of fibrous cartilage. The section is taken from the symphysis pubis, and magnified 155 times.
The development of cartilage is the same with that of cartilage of bone (page 5), the different forms of cartilage resulting from subsequent changes in the intercellular substance and cells. Thus, for example, in articular cartilage the cells undergo the lowest degree of development, are very disproportionate to the intercellular substance, and the latter remains permanently structureless. In reticular cartilage the cells possess a more active growth, and surpass in bulk the intercellular substance, while the latter is composed also of cells, which assume a fibrous disposition. In fibrous cartilage development is most energetic in the intercellular substance; this is converted into fasciculi of fibrous tissue while the interspaces are filled with cells and imperfect fibrous tissue in every stage of development.

**Fibrous Tissue** is one of the most generally distributed of all the animal tissues; it is composed of fibres of extreme minuteness, and presents itself under three elementary forms; namely, white fibrous tissue, yellow fibrous tissue, and red fibrous tissue.

In white fibrous tissue the fibres are cylindrical, exceedingly minute, (about \( \frac{1}{15000} \) of an inch in diameter), transparent and undulating; they are collected into small fasciculi (from \( \frac{3000}{10000} \) to \( \frac{10000}{10000} \) of an inch) and these latter form larger fasciculi, which according to their arrangement give rise to the production of thin laminæ, membranes, ligamentous bands, and tendinous cords. The connecting medium of the fibres in the formation of the primitive fasciculi is a transparent structureless interfibrous substance or blastema, to which in most situations are added numerous minute dark filaments derived from nuclei and thence termed nuclear filaments. The nuclear filaments are sometimes wound spirally around the fasciculi or interlace with their separate fibres, at other times they are variously twisted and run parallel with the fasciculi. The fasciculi are connected and held together in the formation of membranes and cords by loose fibres which are interwoven between them, or by mutual interlacement.

Examples of white fibrous tissue are met with in three principal forms, namely, membrane, ligament, and tendon.

The membranous form of white fibrous tissue is seen in the common connecting medium of the body, namely, fibro-cellular or areolar tissue, in which the membrane is extremely thin and disposed in laminæ, bands or threads, leaving interstices of various size between them. It is seen also in the condensed covering of various organs, as the peristium, perichondrium, capsule propria of glands, membranes of the brain, sclerotic coat of the eyeball, pericardium, fascia; sheaths of muscles, tendons, vessels, nerves and ducts; sheaths of the erectile organs, and the corium of the dermic and mucous membrane.

**Ligament** is the name given to those bands of various breadth and thickness which retain the articular ends of bones in contact in the construction of joints. They are glistening and inelastic and composed of fasciculi of fibrous tissue ranged in a parallel direction side by side, or in some situations interwoven with each other. The fasciculi are held together by separate fibres, or by areolar tissue.
Tendon is the collection of parallel fasciculi of fibrous tissue, by means of which muscles are attached to bones. They are constructed on the same principle with ligaments, are usually rounded in their figure, but in some instances are spread out so as to assume a membranous form. In the latter state they are called aponeuroses.

Yellow fibrous tissue is known also by the appellation elastic tissue, from one of its more prominent physical properties, a property which permits of its fibres being drawn out to double their length and again returning to their original dimensions. The fibres of elastic tissue are transparent, brittle, flat, or polyhedral in shape, colourless when single but yellowish in an aggregated form, and considerably thicker (\( \frac{1}{5000} \) of an inch in diameter) than the fibres of white fibrous tissue. In the construction of their peculiar tissue they communicate with each other by means of short oblique fibres, which unite with adjoining fibres at acute or obtuse angles without any enlargement of the fibre with which they are joined. This circumstance has given rise to the idea of these fibres giving off branches, an expression derived from the division of blood-vessels, and another term borrowed from the same source has been applied to their communication with each other, namely, inosculuation; but both these expressions in their literal meaning are incorrect. When yellow fibrous tissue is cut or torn, the fibres in consequence of their elasticity become clubbed and curved at the extremity, a striking character of this tissue.

The instances of yellow fibrous tissue are; the ligamenta subflava of the arches of the vertebrae, chordæ vocales, thyro-epiglottic ligament, crico-thyroidean membrane, the membranous layers connecting the cartilaginous rings of the trachea and bronchial tubes, the capsula propria of the spleen and the middle coat of arteries. It is also met with around some parts of the alimentary canal, as the oesophagus, cardia, and anus, around the male and female urethra, in the fascia lata, and in the corium of the skin.

Red fibrous tissue is also termed contractile tissue, from a peculiar property which it possesses, and which places it physiologically in an intermediate position between white fibrous tissue and muscular fibre. Its fibres are cylindrical, transparent, reddish in hue, and collected into fasciculi. It is met with in the corium of the skin, in the dartos, around the nipple, in the excretory ducts of glands, in the coats of blood-vessels, particularly veins, in the iris, in the intervascular spaces of the erectile tissue of the penis and clitoris, around the urethra, and around the vagina.

Adipose tissue is composed of minute cells, aggregated together in clusters of various size within the areolas of fibro-cellular tissue. The cells of adipose tissue are identical in manner of formation with other cells, being developed on nuclei and increasing in size by the formation of fluid in their interior. In adipose cells this fluid, instead of being albuminous as in other cells, is oleaginous, the oil at first appearing in separate globules, which subsequently coalesce into a single drop. The size of adipose cells at their full development is about
of an inch in diameter; when isolated they are globular in form, but are hexagonal or polyhedral when compressed. They are perfectly transparent, the cell-membrane being structureless and their nucleus disappearing as they attain their full size.

Synovial Membrane is a thin membranous layer, which invests the articular cartilages of the bones, and is thence reflected upon the surfaces of the ligaments which surround and enter into the composition of a joint. It resembles the serous membranes in being a shut sac, and secretes a transparent and viscous fluid, which is named synovia. Synovia is an alkaline secretion, containing albumen, which is coagulable at a boiling temperature. The continuation of this membrane over the surface of the articular cartilage, a much agitated question, has been decided by the interesting discoveries of Henle, who has ascertained the existence of an epithelium upon cartilage identical with that produced by the reflected portion of the membrane. In some of the joints the synovial membrane is pressed into the articular cavity by a cushion of fat: this mass was called by Havers the synovial gland, from an incorrect supposition that it was the source of the synovia; it is found in the hip and in the knee-joint. In the knee-joint, moreover, the synovial membrane forms folds, which are most improperly named ligaments, as the mucous and alar ligaments, the two latter being an appendage to the cushion of fat. Besides the synovial membranes entering into the composition of joints, there are numerous smaller sacs of a similar kind interposed between surfaces which move upon each other so as to cause friction; they are often associated with the articulations. These are the bursae mucosae; they are shut sacs, analogous in structure to synovial membranes, and secreting a similar synovial fluid.

The epithelium of synovial membranes is of the kind termed tesselated; it is developed in the same manner with the epithelium of other free surfaces, and is continually reproduced from beneath, while the superficial layers are being rubbed off and lost.

ARTICULATIONS.

The joints may be arranged, according to a natural division, into those of the trunk, those of the upper extremity, and those of the lower extremity.

LIGAMENTS OF THE TRUNK.—The articulations of the trunk are divisible into ten groups, viz.—

1. Of the vertebral column.
2. Of the atlas, with the occipital bone.
3. Of the axis, with the occipital bone.
4. Of the atlas, with the axis.
5. Of the lower jaw.
6. Of the ribs, with the vertebrae.
7. Of the ribs, with the sternum, and with each other.
8. Of the sternum.
9. Of the vertebral column, with the pelvis.
10. Of the pelvis.

1. *Articulation of the vertebral Column.*—The ligaments connecting together the different pieces of the vertebral column, admit of the same arrangement with that of the vertebrae themselves. Thus the ligaments

Of the **bodies** are the—

Anterior common ligament,
Posterior common ligament,
Intervertebral substance.

Of the **arches,**—
Ligamenta subflava.

Of the **articular processes,**—
Capsular ligaments,
Synovial membranes.

Of the **spinous processes,**—
Inter-spinous,
Supra-spinous.

Of the **transverse processes,**—
Inter-transverse.

**Bodies**—The *Anterior common ligament* is a broad and riband-like band of ligamentous fibres, extending along the front surface of the vertebral column, from the axis to the sacrum. It is intimately connected with the intervertebral substances, and less closely with the bodies of the vertebrae. In the dorsal region it is thicker than in the cervical and lumbar, and consists of a median and two lateral portions separated from each other by a series of openings for the passage of

*Fig. 50.*

* The anterior ligaments of the vertebrae, and ligaments of the ribs. 1. The anterior common ligament. 2. The anterior costo-vertebral or stellate ligament. 3. The anterior costo-transverse ligament. 4. The interarticular ligament connecting the head of the rib to the intervertebral substance, and separating the two synovial membranes of this articulation.
vessels. The ligament is composed of fibres of various length closely interwoven with each other; the deeper and shorter crossing the intervertebral substances from one vertebra to the next; and the superficial and longer fibres crossing three or four vertebrae.

The anterior common ligament is in relation by its posterior or vertebral surface, with the intervertebral substances, the bodies of the vertebrae, and with the vessels, principally veins, which separate its central from its lateral portions. By its anterior or visceral surface it is in relation in the neck, with the longus colli muscles, the pharynx and the oesophagus; in the thoracic region, with the aorta, the venae azygos, and thoracic duct; and in the lumbar region, with the aorta, right renal artery, right lumbar arteries,arteria sacra media, vena cava inferior, left lumbar veins, receptaculum chyli, the commence ment of the thoracic duct, and the tendons of the lesser muscle of the diaphragm with the fibres of which the ligamentous fibres interlace.

The Posterior common ligament lies upon the posterior surface of the bodies of the vertebrae, and extends from the axis to the sacrum. It is broad opposite the intervertebral substances, to which it is closely adherent; and narrow and thick over the bodies of the vertebrae, from which it is separated by the veins of the base of the vertebra. It is composed like the anterior ligament of shorter and longer fibres which are disposed in a similar manner.

The posterior common ligament is in relation by its anterior surface with the intervertebral substances, the bodies of the vertebrae, and with the venae basum vertebrarum; and by its posterior surface with the dura mater of the spinal cord, some loose areolar tissue and numerous small veins being interposed.

The Intervertebral substance is a lenticular disc of fibrous cartilage, interposed between each of the vertebrae from the axis to the sacrum, and retaining them firmly in connexion with each other. It differs in thickness in different parts of the column, and varies in depth at different points of its extent; thus, it is thickest in the lumbar region, deepest in front in the cervical and lumbar regions, and behind in the dorsal region; and contributes, in a great measure, to the formation of the natural curves of the vertebral column.

* A posterior view of the bodies of three dorsal vertebrae, connected by their intervertebral substance 1, 1. The laminae (2) have been sawn through near the bodies of the vertebrae, and the arches and processes removed, in order to shew (3) the posterior common ligament. A part of one of the openings in the posterior surface of the vertebra, for the transmission of the vena basis
When the intervertebral substance is bisected either horizontally or vertically, it is seen to be composed of a series of layers of dense fibrous tissue, separated by interstices filled with the softer kind. The central part of each intervertebral disc is wholly made up of this softer fibrous cartilage, which has the appearance of a pulp, and is so elastic as to rise above the level of the section as soon as its division is completed. When examined from the front, the layers are found to consist of fibres passing obliquely between the two vertebrae, in one layer passing from left to right, in the next from right to left, alternating in each successive layer.

**Fig. 52.**

Each other at the middle line by a slight interspace. They counteract, by their elasticity, the efforts of the flexor muscles of the trunk; and by preserving the upright position of the spine, limit the expenditure of muscular force. They are longer in the cervical than in the other regions of the spine, and are thickest in the lumbar region.

The ligamenta subflava are in relation by both surfaces with the meningo-rachidian veins, and internally they are separated from the dura mater of the spinal cord by those veins and some loose areolar and adipose tissue.

**Articular Processes.**—The ligaments of the articular processes of the vertebrae are loose synovial capsules which surround the articulating surfaces. They are protected on their external side by a thin layer of ligamentous fibres.

**Spinous Processes.**—The inter-spinous ligaments are thin and membranous, and are extended between the spinous processes in the dorsal and lumbar regions. They are thickest in the latter region; and are in relation with the multifidus spine muscle at each side.

Vertebrae, is seen at 4, by the side of the narrow and unattached portion of the ligament.

*An internal view of the arches of three vertebrae. To obtain this view the laminae have been divided through their pedicles. 1. One of the ligamenta subflava. 2. The capsular ligament of one side.*
LIGAMENTS OF THE VERTEBRAL COLUMN.

The *Supra-spinous* ligament (fig. 60) is a strong and inelastic fibrous cord, which extends from the apex of the spinous process of the last cervical vertebra to the sacrum, being attached to each spinous process in its course; it is thickest in the lumbar region. The continuation of this ligament upwards to the tuberosity of the occipital bone, constitutes the rudimentary ligamentum nuchæ of man. The latter is strengthened, as in animals, by a thin slip from the spinous process of each of the cervical vertebrae.

**Transverse Processes.**—The *inter-transverse ligaments* are thin and membranous; they are found only between the transverse processes of the lower dorsal vertebrae.

2. **Articulation of the Atlas with the Occipital bone.**—The ligaments of this articulation are seven in number,—

Two anterior occipito-atloid,
Posterior occipito-atloid,
Lateral occipito-atloid,
Two capsular.

Of the two *anterior ligaments* one is a rounded cord, situated in the middle line, and superficially to the other. It is attached above, to

* An anterior view of the ligaments connecting the atlas, the axis, and the occipital bone. A transverse section has been carried through the base of the skull, dividing the basilar process of the occipital bone and the petrous portions of the temporal bones. 1. The anterior round occipito-atloid ligament. 2. The anterior broad occipito-atloid ligament. 3. The commencement of the anterior common ligament. 4. The anterior atlo-axoid ligament, which is continuous inferiorly with the commencement of the anterior common ligament. 5. One of the atlo-axoid capsular ligaments; the one on the opposite side has been removed, to shew the approximated surfaces of the articular processes (6). 7. One of the occipito-atloid capsular ligaments. The most external of these fibres constitute the lateral occipito-atloid ligament.
the basilar process of the occipital bone; and below, to the anterior tubercle of the atlas. The deeper ligament is a broad membranous layer, attached above, to the margin of the occipital foramen; and below, to the whole length of the anterior arch of the atlas. It is in relation in front with the recti antici minores and behind with the odontoid ligaments.

The posterior ligament is thin and membranous; it is attached above, to the margin of the occipital foramen; and below, to the posterior arch of the atlas. It is closely adherent to the dura mater, by its inner surface; and forms a ligamentous arch at each side, for the passage of the vertebral arteries and first cervical nerves. It is in relation posteriorly with the recti postici minores and obliqui superiores.

The lateral ligaments are strong fasciculi of ligamentous fibres, attached below, to the base of the transverse process of the atlas at each side, and above to the transverse process of the occipital bone. With a ligamentous expansion derived from the vaginal process of the temporal bone, these ligaments form a strong sheath around the vessels and nerves which pass through the carotid and jugular foramina.

The capsular ligaments are the thin and loose ligamentous capsules, which surround the synovial membranes of the articulations between the condyles of the occipital bone and the superior articular processes of the atlas. The ligamentous fibres are most numerous upon the anterior and external part of the articulation.

* The posterior ligaments of the occipito- atl oid, and atl o- axoid articulations. 1. The atlas. 2. The axis. 3. The posterior ligament of the occipito- atl oid articulation. 4. The capsular and lateral ligaments of this articulation. 5. The posterior ligament of the atl o- axoid articulation. 6, 6. Its capsular ligaments. 7. The first of the ligamenta subflava passing between the axis and the third cervical vertebra. 8, 8. The capsular ligaments of those vertebrae.
The movements taking place between the cranium and atlas, are those of flexion and erection, giving rise to the forward nodding of the head. When this motion is increased to any extent the whole of the cervical region concurs in its production.

3. Articulation of the Axis with the Occipital bone.—The ligaments of this articulation are three in number,—

Occipito-axoid,
Two odontoid.

The occipito-axoid ligament (apparatus ligamentosus colli) is a broad band, which covers in the odontoid process and its ligaments. It is attached below to the body of the axis, where it is continuous with the posterior common ligament; superiorly it is inserted by a broad expansion, into the basilar groove of the occipital bone. It is firmly connected opposite the body of the axis, with the dura mater; and sometimes is described as consisting of a central and two lateral portions; this however is an unnecessary refinement.

The odontoid ligaments (alar) are two short and thick fasciculi of fibres, which pass outwards from the apex of the odontoid process, to the sides of the occipital foramen and condyles. A third and smaller fasciculus (ligamentum suspensorium) proceeds from the apex of the odontoid process to the anterior margin of the foramen magnum.

These ligaments serve to limit the extent to which rotation of the head may be carried, hence they are termed check ligaments.

* The upper part of the vertebral canal, opened from behind in order to shew the occipito-axoid ligament. 1. The basilar portion of the sphenoid bone. 2. Section of the occipital bone. 3. The atlas, its posterior arch removed. 4. The axis, the posterior arch also removed. 5. The occipito-axoid ligament, rendered prominent at its middle by the projection of the odontoid process. 6. Lateral and capsular ligament of the occipito-atloid articulation. 7. Cap- sular ligament between the articulating processes of the atlas and axis.
4. *Articulation of the Atlas with the Axis.*—The ligaments of this articulation are five in number,—

- Anterior atlo-axoid,
- Posterior atlo-axoid,
- Two capsular,
- Transverse.

The *anterior ligament* consists of ligamentous fibres, which pass from the anterior tubercle and arch of the atlas to the base of the odontoid process and body of the axis, where they are continuous with the commencement of the anterior common ligament.

The *posterior ligament* is a thin and membranous layer, passing between the posterior arch of the atlas and the laminae of the axis.

The *capsular ligaments* surround the articular processes of the atlas and axis; they are loose, to permit of the freedom of movement which subsists between these vertebrae. The ligamentous fibres are most numerous on the outer and anterior part of the articulation, and the synovial membrane usually communicates with the synovial cavity between the transverse ligament and the odontoid process.

The *transverse ligament* is a strong ligamentous band, which arches across the area of the ring of the atlas from a rough tubercle upon the inner surface of one articular process to a similar tubercle on the other. It serves to retain the odontoid process of the axis, in connection with the anterior arch of the atlas. As it crosses the odontoid process,

* A posterior view of the ligaments connecting the atlas, the axis, and the occipital bone. The posterior part of the occipital bone has been sawn away, and the arches of the atlas and axis removed. 1. The superior part of the occipito-axoid ligament, which has been cut away in order to shew the ligaments beneath. 2. The transverse ligament of the atlas. 3, 4. The ascending and descending slips of the transverse ligament, which have obtained for it the title of cruciform ligament. 5. One of the odontoid ligaments; the fellow ligament is seen on the opposite side. 6. One of the occipito-atloid capsular ligaments. 7. One of the atlo-axoid capsular ligaments.
some fibres are sent downwards to be attached to the body of the axis, and others pass upwards to be inserted into the basilar process of the occipital bone; hence the ligament has a cross-like appearance, and has been denominated cruciform. A synovial membrane is situated between the transverse ligament and the odontoid process; and another between that process and the inner surface of the anterior arch of the atlas.

Actions.—It is the peculiar disposition of this ligament in relation to the odontoid process, that enables the atlas, and with it the entire cranium, to rotate upon the axis; the perfect freedom of movement between these bones being ensured by the two synovial membranes. The lower part of the ring, formed by the transverse ligament with the atlas, is smaller than the upper, while the summit of the odontoid process is larger than its base; so that the process is still retained in its position by the transverse ligament, when the other ligaments are cut through. The extent to which the rotation of the head upon the axis can be carried is determined by the odontoid ligaments. The odontoid process with its ligaments is covered in by the occipito-axoid ligament.

5. Articulation of the Lower Jaw.—The lower jaw has properly but one ligament, the external lateral; the ligaments usually described are three in number; to which may be added, as appertaining to the mechanism of the joint, an interarticular fibrous-cartilage, and two synovial membranes,—

External lateral,
Internal lateral,
Capsular.
Interarticular fibrous-cartilage,
Two synovial membranes.

Fig. 57.*

* An external view of the articulation of the lower jaw. 1. The zygomatic arch. 2. The tubercle of the zygoma. 3. The ramus of the lower jaw. 4. The mastoid portion of the temporal bone. 5. The external lateral ligament. 6. The stylo-maxillary ligament.
The external lateral ligament is a short and thick band of fibres, passing obliquely backwards from the tubercle of the zygoma, to the external surface of the neck of the lower jaw. It is in relation, externally with the integument of the face, and internally with the two synovial membranes of the articulation and the interarticular cartilage. The external lateral ligament acts conjointly with its fellow of the opposite side of the head in the movements of the jaw.

The internal lateral ligament has no connection with the articulation of the lower jaw, and is incorrectly named in relation to the joint; it is a thin aponeurotic expansion extending from the extremity of the spinous process of the sphenoid bone to the margin of the dental foramen. It is pierced at its insertion, by the mylo-hyoidian nerve.

A triangular space is left between the internal lateral ligament and the neck of the jaw, in which are situated the internal maxillary artery and auricular nerve, the inferior dental artery and nerve, and a part of the external pterygoid muscle; internally it is in relation with the internal pterygoid muscle.

The capsular ligament consists of a few irregular ligamentous fibres,

which pass from the edge of the glenoid cavity to the neck of the lower jaw, upon the inner and posterior side of the articulation. These fibres scarcely deserve consideration as a distinct ligament.

The interarticular fibrous cartilage is a thin oval plate, thicker at the edges than in the centre, and placed horizontally between the head of the condyle of the lower jaw and the glenoid cavity. It is connected

* An internal view of the articulation of the lower jaw. 1. A section through the petrous portion of the temporal bone and spinous process of the sphenoid. 2. by its outer border with the external lateral ligament, and in front receives some fibres of insertion of the external pterygoid muscle. Occasionally it is incomplete in the centre. It divides the joint into two distinct cavities, the one being above and the other below the cartilage.

The synovial membranes are situated the one above, the other below the fibrous-cartilage, the former being the larger of the two. When the fibrous-cartilage is perforate, the synovial membranes communicate.

Besides the lower jaw, there are several other joints provided with a complete interarticular cartilage, and, consequently, with two synovial membranes; they are, the sterno-clavicular articulation, the acromio-clavicular and the articulation of the ulna with the cuneiform bone.

The interarticular fibrous-cartilages of the knee-joint are partial, and there is but one synovial membrane.

The articulations of the heads of the ribs with the vertebrae have two synovial membranes, separated by an interarticular ligament without fibrous-cartilage.

* Fig. 59.*

Actions.—The movements of the lower jaw are depression, by which the mouth is opened; elevation, by which it is closed; a forward and backward movement, and a movement from side to side.

In the movement of depression the interarticular cartilage glides for-

* In this sketch a section has been carried through the joint, in order to shew the natural position of the interarticular fibro-cartilage, and the manner in which it is adapted to the difference of form of the articulating surfaces. 1. The glenoid fossa. 2. The eminentia articularis. 3. The interarticular fibro-cartilage. 4. The superior synovial cavity. 5. The inferior synovial cavity. 6. An interarticular fibro-cartilage, removed from the joint, in order to shew its oval and concave form; it is seen from below.
wards on the eminentia articularis, carrying with it the condyle. If this movement be carried too far, the superior synovial membrane is ruptured, and dislocation of the fibro-cartilage with its condyle into the zygomatic fossa occurs. In elevation the fibrous cartilage and condyle are returned to their original position. The forward and backward movement is a gliding of the fibro-cartilage upon the glenoid articular surface, in the antero-posterior direction; and the movement from side to side, in the lateral direction.

6. Articulation of the Ribs with the Vertebrae.—The ligaments of these articulations are so strong as to render dislocation impossible, the neck of the rib would break before displacement could occur; they are divisible into two groups:—1. Those connecting the head of the rib with the bodies of the vertebra; and, 2. Those connecting the neck and tubercle of the rib with the transverse processes. They are

1st Group.
Anterior costo-vertebral or stellate,
Capsular,
Interarticular ligament,
Two synovial membranes.

2nd Group.
Anterior costo-transverse,
Middle costo-transverse,
Posterior costo-transverse.

The anterior costo-vertebral or stellate ligament (fig. 50) consists of three short bands of ligamentous fibres that radiate from the anterior part of the head of the rib. The superior band passes upwards, and is attached to the vertebra above; the middle fasciculus is attached to the intervertebral substance; and the inferior, to the vertebra below.

In the first, eleventh, and twelfth ribs, the three fasciculi are attached to the body of the corresponding vertebra.

The capsular ligament is a thin layer of ligamentous fibres surrounding the joint in the interval left by the anterior ligament; it is thickest above and below the articulation, and protects the synovial membranes.

The interarticular ligament is a thin band which passes between the sharp crest on the head of the rib and the intervertebral substance. It divides the joint into two cavities, which are each furnished with a separate synovial membrane. The first, eleventh, and twelfth ribs have no interarticular ligament, and consequently but one synovial membrane.

The anterior costo-transverse ligament is a broad band composed of several fasciculi, which ascend from the crest-like ridge on the neck of the rib, to the transverse process immediately above. This ligament
separates the anterior from the posterior branch of the intercostal nerves.

The middle costo-transverse ligament is a very strong interosseous ligament passing directly between the posterior surface of the neck of the rib, and the transverse process against which it rests.

The posterior costo-transverse ligament is a small but strong fasciculus, passing obliquely from the tubercle of the rib, to the apex of the transverse process. The articulation between the tubercle of the rib and the transverse process is provided with a small synovial membrane.

There is no anterior costo-transverse ligament to the first rib; and only rudimentary posterior costo-transverse ligaments to the eleventh and twelfth ribs.

Actions.—The movements permitted by the articulations of the ribs, are upwards and downwards, and slightly forwards and backwards; the movement increasing in extent from the head to the extremity of the rib. The forward and backward movement is very trifling in the seven superior, but greater in the inferior ribs; the eleventh and twelfth are very movable.

7. Articulation of the Ribs with the Sternum, and with each other.—The ligaments of the costo-sternal articulations are,—

Anterior costo-sternal,
Posterior costo-sternal,
Superior costo-sternal,
Inferior costo-sternal,
Synovial membranes.

The anterior costo-sternal ligament is a thin band of ligamentous fibres, that passes in a radiated direction from the extremity of the costal cartilage to the anterior surface of the sternum, and intermingles its fibres with those of the ligament of the opposite side and with the tendinous fibres of origin of the pectoralis major muscle.

The posterior costo-sternal ligament is much smaller than the anterior, and consists only of a thin fasciculus of fibres situated on the posterior surface of the articulation.

* A posterior view of a part of the thoracic portion of the vertebral column, shewing the ligaments connecting the vertebrae with each other and the ribs with the vertebrae. 1, 1. The supra-spinous ligament. 2, 2. The ligamenta subflava, connecting the laminae. 3. The anterior costo-transverse ligament. 4. The posterior costo-transverse ligaments.
The superior and inferior costo-sternal ligaments are narrow fasciculi corresponding with the breadth of the cartilage, and connecting its superior and inferior border with the side of the sternum.

The synovial membrane is absent in the articulation of the first rib, its cartilage being usually continuous with the sternum; that of the second rib has an inter-articular ligament, with two synovial membranes.

The sixth and seventh ribs have several fasciculi of strong ligamentous fibres, passing from the extremity of their cartilages to the anterior surface of the ensiform cartilage, which latter they are intended to support. They are named the costo-xiphoid ligaments.

The sixth, seventh, and eighth, and sometimes the fifth and the ninth costal cartilages, have articulations with each other, and a perfect synovial membrane. They are connected by ligamentous fibres which pass from one cartilage to the other, external and internal ligaments.

The ninth and tenth are connected at their extremities by ligamentous fibres, but have no synovial membranes.

Actions.—The movements of the costo-sternal articulations are very trifling; they are limited to a slight sliding motion. The first rib is the least, and the second the most movable.

8. Articulation of the Sternum.—The pieces of the sternum are connected by means of a thin plate of interosseous cartilage placed between each, and by an anterior and posterior ligament. The fibres of the anterior sternal ligament are longitudinal in direction, but so blended with the anterior costo-sternal ligaments, and the tendinous fibres of origin of the pectoral muscles as scarcely to be distinguished as a distinct ligament. The posterior sternal ligament is a broad smooth plane of longitudinal fibres, placed upon the posterior surface of the bone, and extending from the manubrium to the ensiform cartilage. These ligaments contribute very materially to the strength of the sternum and to the elasticity of the front of the chest.

9. Articulation of the Vertebral Column with the Pelvis.—The last lumbar vertebra is connected with the sacrum by the same ligaments with which the various vertebrae are connected to each other; viz. the anterior and posterior common ligaments, intervertebral substance, ligamenta subflava, capsular ligaments, and inter and supra-spinous ligaments.

There are, however, two proper ligaments connecting the vertebral column with the pelvis; these are, the

Lumbo-sacral,
Lumbo-iliac.

The lumbo-sacral ligament is a thick triangular fasciculus of ligamentous fibres, connected above, with the transverse process of the last lumbar vertebra; and below with the posterior part of the upper border of the sacrum.

The lumbo-iliac ligament passes from the apex of the transverse process of the last lumbar vertebra to that part of the crest of the
ilium which surmounts the sacro-iliac articulation. It is triangular in form.

10. The Articulations of the Pelvis.—The ligaments belonging to the articulations of the pelvis are divisible into four groups:—1. Those connecting the sacrum and ilium; 2. those passing between the sacrum and ischium; 3. between the sacrum and coccyx; and 4, between the two pubic bones.

1st, Between the sacrum and ilium.
   Sacro-iliac anterior,
   Sacro-iliac posterior.

2nd, Between the sacrum and ischium.
   Sacro-ischiatic anterior (short),
   Sacro-ischiatic posterior (long).

3rd, Between the sacrum and coccyx.
   Sacro-coccygean anterior,
   Sacro-coccygean posterior.

4th, Between the ossa pubis.
   Anterior pubic,
   Posterior pubic,
   Superior pubic,
   Sub-pubic,
   Interosseous fibro-cartilage.

1. Between the Sacrum and Ilium.—The anterior sacro-iliac ligament consists of numerous short ligamentous fibres, which pass from bone to bone on the anterior surface of the joint.

   The posterior sacro-iliac or interosseous ligament is composed of numerous strong fasciuli of ligamentous fibres, which pass horizontally between the rough surfaces in the posterior half of the sacro-iliac articulation, and constitute the principal bond of connection between the sacrum and the ilium. One fasciculus of this ligament, longer and larger than the rest, is distinguished from its direction, by the name of the oblique sacro-iliac ligament. It is attached, by one extremity, to the posterior superior spine of the ilium; and, by the other, to the third transverse tubercle on the posterior surface of the sacrum.

   The surfaces of the two bones forming the sacro-iliac articulation, are partly covered with cartilage, and partly rough and connected by the interosseous ligament. The anterior or auricular half is coated with cartilage, which is thicker on the sacrum than on the ilium. The surface of the cartilage is irregular, and provided with a very delicate synovial membrane, which cannot be demonstrated in the adult; but is apparent in the young subject, and in the female during pregnancy.

2. Between the Sacrum and Ischium.—The anterior or lesser sacro-ischiatic ligament is thin, and triangular in form; it is attached by its apex to the spine of the ischium; and by its broad extremity to the
side of the sacrum and coccyx, interlacing its fibres with the greater sacro-ischiatic ligament.

The anterior sacro-ischiatic ligament is in relation in front with the coccygeus muscle, and behind with the posterior ligament, with which its fibres are intermingled. By its upper border it forms a part of the lower boundary of the great sacro-ischiatic foramen, and by the lower a part of the lesser sacro-ischiatic foramen.

The posterior or greater sacro-ischiatic ligament, considerably larger, thicker, and more posterior than the preceding, is narrower in the middle than at each extremity. It is attached, by its smaller end, to the inner margin of the tuberosity and ramus of the ischium, where it forms a falciform process, which protects the internal pudic artery, and is continuous with the obturator fascia. By its larger extremity it is inserted into the side of the coccyx, sacrum, and posterior inferior spine of the ilium.

The posterior sacro-ischiatic ligament is in relation in front with the anterior ligament, and behind with the gluteus maximus, to some of the fibres of which it gives origin. By its superior border it forms

* The ligaments of the pelvis and hip-joint. 1. The lower part of the anterior common ligament of the vertebrae, extending downwards over the front of the sacrum. 2. The lumbo-sacral ligament. 3. The lumbo-iliac ligament. 4. The anterior sacro-iliac ligaments. 5. The obturator membrane. 6. Poupart's ligament. 7. Gimbernat's ligament. 8. The capsular ligament of the hip-joint. 9. The ilio-femoral or accessory ligament.
part of the lesser ischiatic foramen, and by its lower border, a part of the boundary of the perineum. It is pierced by the coccygeal branch of the ischiatic artery. The two ligaments convert the sacro-ischiatic notches into foramina.

3. Between the Sacrum and Coccyx.—The anterior sacro-coccygean ligament is a thin fasciculus passing from the anterior surface of the sacrum to the front of the coccyx.

The posterior sacro-coccygean ligament is a thick ligamentous layer, which completes the lower part of the sacral canal, and connects the sacrum with the coccyx posteriorly, extending as far as the apex of the latter bone.

Between the two bones is a thin disc of soft fibrous cartilage. In females there is frequently a small synovial membrane. This articulation admits of a certain degree of movement backwards during parturition.

* Ligaments of the pelvis and hip-joint. The view is taken from the side.
1. The oblique sacro-iliac ligament. The other fasciculi of the posterior sacro-iliac ligaments are not seen in this view of the pelvis. 2. The posterior sacro-ischiatic ligament. 3. The anterior sacro-ischiatic ligament. 4. The great sacro-ischiatic foramen. 5. The lesser sacro-ischiatic foramen. 6. The cotyloidal ligament of the acetabulum. 7. The ligamentum teres. 8. The cut edge of the capsular ligament, shewing its extent posteriorly as compared with its anterior attachment. 9. The obturator membrane only partly seen.
The ligaments connecting the different pieces of the coccyx consist of a few scattered anterior and posterior fibres, and a thin disc of interosseous cartilage; they exist only in the young subject, in the adult the pieces become ossified.

4. Between the Ossa Pubis.—The anterior pubic ligament is composed of ligamentous fibres, which pass obliquely across the union of the two bones from side to side, and form an interlacement in front of the symphysis.

The posterior pubic ligament consists of a few irregular fibres unifying the pubic bones posteriorly.

The superior pubic ligament is a thick band of fibres connecting the angles of the pubic bones superiorly, and filling the inequalities upon the surface of the bones.

The sub-pubic ligament is a thick arch of fibres connecting the two bones inferiorly, and forming the upper boundary of the pubic arch.

The interosseous fibro-cartilage unites the two surfaces of the pubic bones, in the same manner as the intervertebral substance connects the bodies of the vertebrae. It resembles the intervertebral substance also in being composed of oblique fibres disposed in concentric layers, which are more dense towards the surface than near the centre. It is thick in front, and thin behind. A synovial membrane is sometimes found in the posterior half of the articulation.

This articulation becomes movable towards the latter term of pregnancy, and admits of a slight degree of separation of its surfaces.

The obturator ligament or membrane is not a ligament of articulation, but simply a tendino-fibrous membrane stretched across the obturator foramen. It gives attachment by its surfaces, to the two obturator muscles, and leaves a space in the upper part of the foramen, for the passage of the obturator vessels and nerve.

The numerous vacuities in the walls of the pelvis, and their closure by ligamentous structures, as in the case of the sacro-ischiatic fissures and obturator foramina, serve to diminish very materially the pressure on the soft parts during the passage of the head of the foetus through the pelvis in parturition.

LIGAMENTS OF THE UPPER EXTREMITY.

The Ligaments of the upper extremity may be arranged in the order of the articulations between the different bones; they are, the

1. Sterno-clavicular articulation.
2. Scapulo-clavicular articulation.
3. Ligaments of the scapula.
4. Shoulder joint.
5. Elbow joint.
6. Radio-ulnar articulation.
7. Wrist joint.
STERNO-CLAVICULAR LIGAMENTS.

8. Articulation between the carpal bones.
10. Metacarpo-phalangeal articulation.
11. Articulation of the phalanges.

1. Sterno-clavicular Articulation.—The sterno-clavicular is an arthro-dial articulation; its ligaments are,

- Anterior sterno-clavicular,
- Posterior sterno-clavicular,
- Inter-clavicular,
- Costo-clavicular (rhomboid),
- Interarticular fibro-cartilage,
- Two synovial membranes.

The anterior sterno-clavicular ligament is a broad ligamentous layer, extending obliquely downwards and forwards, and covering the anterior aspect of the articulation. This ligament is in relation by its anterior surface with the integument and with the sternal origin of the sterno-mastoid muscle; and behind with the interarticular fibro-cartilage and synovial membranes.

The posterior sterno-clavicular ligament is a broad fasciculus, covering the posterior surface of the articulation. It is in relation by its anterior surface with the interarticular fibro-cartilage and synovial membranes, and behind with the sterno-hyoid muscle.

The two ligaments are continuous at the upper and lower part of the articulation, so as to form a complete capsule around the joint.

The inter-clavicular ligament is a cord-like band which crosses from the extremity of one clavicle to the other, and is closely connected with the upper border of the sternum. It is separated by areolar tissue from the sterno-thyroid muscles.

The costo-clavicular ligament (rhomboid) is a thick fasciculus of fibres, connecting the sternal extremity of the clavicle with the cartilage of the first rib. It is situated obliquely between the rib and the under surface of the clavicle. It is in relation in front with the tendon of origin of the subclavius muscle, and behind with the subclavian vein.

Actions.—The movements of the sterno-clavicular articulation, are a gliding movement of the fibro-cartilage with the clavicle upon the articular surface of the sternum in the directions forwards, backwards, upwards, and downwards; and circumduction. This articulation is the centre of the movements of the shoulder.

It is the rupture of the rhomboid ligament in dislocation of the sternal end of the clavicle that gives rise to the deformity peculiar to this accident.

The interarticular fibro-cartilage is nearly circular in form, and thicker at the edges than in the centre. It is attached above to the clavicle; below to the cartilage of the first rib; and throughout the rest of its circumference to the anterior and posterior sterno-clavicular
ligaments; it divides the joint into two cavities, which are lined by distinct synovial membranes. This cartilage is sometimes pierced through its centre, and not unfrequently deficient, to a greater or less extent, in its lower part.

2. Scapulo-clavicular Articulation.—The ligaments of the scapular end of the clavicle are, the

Superior acromio-clavicular,
Inferior acromio-clavicular,
Coraco-clavicular (trapezoid and conoid),
Interarticular fibro-cartilage,
Two synovial membranes.

The superior acromio-clavicular ligament is a moderately thick plane of superimposed fibres passing between the extremity of the clavicle and the acromion, upon the upper surface of the joint.

The inferior acromio-clavicular ligament is a thin plane situated upon the under surface. These two ligaments are continuous with each other in front and behind, and form a complete capsule around the joint.

The coraco-clavicular ligament (trapezoid, conoid) is a thick fasciculus of ligamentous fibres, passing obliquely between the base of the coracoid process and the under surface of the clavicle, and holding the end of the clavicle in firm connection with the scapula. When seen from before, it has a quadrilateral form: hence it is named trapezoid; and, examined from behind, it has a triangular form, the base being upwards; hence another name, conoid.

The interarticular fibro-cartilage is often indistinct, from having

partial connections with the fibro-cartilaginous surfaces of the two bones between which it is placed, and not unfrequently absent. When partial, it occupies the upper part of the articulation. The synovial membranes are very delicate. There is, of course, but one, when the fibro-cartilage is incomplete.

*Fig. 64.*

**Actions.**—The acromio-clavicular articulation admits of two movements, the gliding of the surfaces upon each other; and the rotation of the scapula, upon the extremity of the clavicle.

3. The **Proper ligaments of the Scapula** are the

Coraco-acromial,

Transverse.

The *coraco-acromial ligament* is a broad and thick triangular band, which forms a protecting arch over the shoulder joint. It is attached by its apex to the point of the acromion process, and by its base to the external border of the coracoid process its whole length. This ligament is *in relation* above with the under surface of the deltoid muscle; and below with the tendon of the supra-spinatus muscle, a bursa mucosa being usually interposed.

* The ligaments of the scapula and shoulder joint. 1. The superior acromio-clavicular ligament. 2. The coraco-clavicular ligament; this aspect of the ligament is named trapezoid. 3. The coraco-acromial ligament. 4. The transverse ligament. 5. The capsular ligament. 6. The coraco-humeral ligament. 7. The long tendon of the biceps issuing from the capsular ligament, and entering the bicipital groove.
The transverse or coracoid ligament is a narrow but strong fasciculus which crosses the notch in the upper border of the scapula, from the base of the coracoid process, and converts it into a foramen. The supra-scapular nerve passes through this foramen.

4. Shoulder Joint. — The scapulo-humeral articulation is an arthrosis, or ball and socket joint—its ligaments are, the

Capsular,
Coraco-humeral,
Glenoid.

The capsular ligament completely encircles the articulating head of the scapula and the head of the humerus, and is attached to the neck of each bone. It is thick above, where resistance is most required, and is strengthened by the tendons of the supra-spinatus, infra-spinatus, teres minor, and subscapularis muscles: below it is thin and loose. The capsule is incomplete at the point of contact with the tendons, so that they obtain upon their inner surface a covering of synovial membrane.

The coraco-humeral ligament is a broad band which descends obliquely outwards from the border of the coracoid process to the greater tuberosity of the humerus, and serves to strengthen the superior and anterior part of the capsular ligament.

The glenoid ligament is the prismoid band of fibro-cartilage, which is attached around the margin of the glenoid cavity for the purposes of protecting its edges, and deepening its cavity. It divides superiorly into two slips which are continuous with the long tendon of the biceps; hence the ligament is frequently described as being formed by the splitting of that tendon. The cavity of the articulation is traversed by the long tendon of the biceps, which is enclosed in a sheath of synovial membrane in its passage through the joint.

The synovial membrane of the shoulder joint is very extensive; it communicates anteriorly through an opening in the capsular ligament with a large bursal sac, which lines the under surface of the tendon of the subscapularis muscle. Superiorly, it frequently communicates through another opening in the capsular ligament with a bursal sac.
ELBOW JOINT.

belonging to the infra-spinatus muscle; and it moreover forms a sheath around that portion of the tendon of the biceps, which is included within the joint.

The muscles immediately surrounding the shoulder joint are the subscapularis, supra-spinatus, infra-spinatus, teres minor, long head of the triceps and deltoid; the long tendon of the biceps is within the capsular ligament.

**Actions.**—The shoulder joint is capable of every variety of motion, viz. of movement forwards and backwards, of abduction and adduction, of circumduction and rotation.

5. **Elbow Joint.**—The elbow is a ginglymoid articulation; its ligaments are four in number,—

Anterior,
Posterior,
Internal lateral,
External lateral.

The *anterior ligament* is a broad and thin membranous layer, descending from the anterior surface of the humerus, immediately above the joint, to the coronoid process of the ulna and orbicular ligament. On each side it is connected with the lateral ligaments. It is composed of fibres which pass in three different directions, vertical, transverse, and oblique, the latter being extended from within outwards to the orbicular ligament, into which they are attached inferiorly. This ligament is covered in by the brachialis anticus muscle.

The *posterior ligament* is a broad and loose layer passing between the posterior surface of the humerus and the anterior surface of the base of the olecranon, and connected at each side with the lateral ligaments. It is covered in by the tendon of the triceps.

The *internal lateral ligament* is a thick triangular layer, attached above, by its apex, to the internal condyle of the humerus; and below, by its expanded border, to the margin of the greater sigmoid cavity of the ulna, extending from the coronoid process to the olecranon. At its insertion it is intermingled with some transverse fibres.

* An external view of the elbow joint. 1. The humerus. 2. The ulna. 3. The radius. 4. The external lateral ligament inserted inferiorly into (5) the orbicular ligament. 6. The posterior extremity of the orbicular ligament, spreading out at its insertion into the ulna. 7. The anterior ligament, scarcely apparent in this view of the articulation. 8. The posterior ligament, thrown into folds by the extension of the joint.
The internal lateral ligament is in relation posteriorly with the ulnar nerve.

The *external lateral ligament* is a strong and narrow band, which descends from the external condyle of the humerus, to be inserted into the orbicular ligament, and into the ridge on the ulna, with which the posterior part of the latter ligament is connected. This ligament is closely united with the tendon of origin of the supinator brevis muscle.

The *synovial membrane* is extensive, and is reflected from the cartilaginous surfaces of the bones upon the inner surface of the ligaments. It surrounds inferiorly the head of the radius, and forms an articulating sac between it and the lesser sigmoid notch.

The muscles immediately surrounding, and in contact with, the elbow joint, are *in front*, the brachialis anticus; *to the inner side*, the pronator radii teres, flexor sublimis digitorum, and flexor carpi ulnaris; *externally*, the extensor carpi radialis brevior, extensor communis digitorum, extensor carpi ulnaris, anconeus, and supinator brevis; and *behind*, the triceps.

Actions.—The movements of the elbow joint are *flexion* and *extension*, which are performed with remarkable precision. The extent to which these movements are capable of being effected, is limited, in front by the coronoid process, and behind by the olecranon.

6. The *Radio-ulnar Articulation.*—The radius and ulnar are firmly held together by ligaments which are connected with both extremities of the bones, and with the shaft; they are, the

<table>

</thead>
<tbody>
<tr>
<td>Oblique,</td>
<td>Posterior inferior,</td>
</tr>
<tr>
<td>Interosseous,</td>
<td>Interarticular fibro-cartilage.</td>
</tr>
</tbody>
</table>

The *orbicular ligament* (*annular, coronary*) is a firm band several lines in breadth, which surrounds the head of the radius, and is attached by each end to the extremities of the lesser sigmoid cavity. It is strongest behind where it receives the external lateral ligament, and is lined on its inner surface by a reflection of the synovial membrane of the elbow joint.

The rupture of this ligament permits of the dislocation of the head of the radius.

The *oblique ligament* (called also ligamentum teres in contradistinction from the interosseous ligament) is a narrow slip of ligamentous fibres, descending obliquely from the base of the coronoid process of the ulna to the inner side of the radius, a little below its tuberosity.

The *interosseous ligament* is a broad and thin plane of aponeurotic fibres passing obliquely downwards from the sharp ridge on the radius to that on the ulna. It is deficient superiorly, is broader in the middle than at each extremity, and is perforated at its lower part for the passage of the anterior interosseous artery. The posterior interosseous artery passes backwards between the oblique ligament and the upper
border of the interosseous ligament. This ligament affords an extensive surface for the attachment of muscles.

The interosseous ligament is in relation, in front, with the flexor profundus digitorum, the flexor longus pollicis, and pronator quadratus muscle, and with the anterior interosseous artery and nerve; and behind with the supinator brevis, extensor ossis metacarpi pollicis, extensor primi intermodii pollicis, extensor secundi intermodii pollicis, and extensor indicis muscle, and near the wrist with the anterior interosseous artery and posterior interosseous nerve.

The anterior inferior ligament is a thin fasciculus of fibres, passing transversely between the radius and ulna.

The posterior inferior ligament is also thin and loose, and has the same disposition on the posterior surface of the articulation.

The interarticular, or triangular fibro-cartilage, acts the part of a ligament between the lower extremities of the radius and ulna. It is attached by its apex to a depression on the inner surface of the styloid process of the ulna, and by its base to the edge of the radius. This fibro-cartilage is lined upon its upper surface by a synovial membrane, which forms a duplicature between the radius and ulna, and is called the membrana sacciformis. By its lower surface it enters into the articulation of the wrist-joint.

Actions.—The movements taking place between the radius and the ulna are, the rotation of the former upon the latter; rotation forwards being termed pronation, and rotation backwards supination. In these movements the head of the radius turns upon its own axis, within the orbicular ligament and the lesser sigmoid notch of the ulna; while inferiorly the radius presents a concavity which moves upon the rounded head of the ulna. The movements of the radius are chiefly limited by the anterior and posterior inferior ligaments, hence these are not unfrequently ruptured in great muscular efforts.

7. Wrist Joint.—The wrist is a ginglymoid articulation; the articular surfaces entering into its formation being the radius and under surface of the triangular fibro-cartilage above, and the rounded surfaces of the scaphoid, semilunar, and cuneiform bone below; its ligaments are four in number,—

<table>
<thead>
<tr>
<th>Anterior,</th>
<th>Internal lateral,</th>
</tr>
</thead>
<tbody>
<tr>
<td>Posterior,</td>
<td>External lateral,</td>
</tr>
</tbody>
</table>

The anterior ligament is a broad and membranous layer consisting of three fasciculi, which pass between the lower part of the radius, and the scaphoid, semilunar, and cuneiform bone.

The posterior ligament, also thin and loose, passes between the posterior surface of the radius, and the posterior surface of the semilunar and cuneiform bone.

The internal lateral ligament extends from the styloid process of the ulna to the cuneiform and pisiform bone.

The external lateral ligament is attached by one extremity to the styloid process of the radius, and by the other to the side of the sca-
phoid bone. The radial artery rests on this ligament as it passes backwards to the first metacarpal space.

The synovial membrane of the wrist joint lines the under surface of the radius and interarticular cartilage above, and the first row of bones of the carpus below.

The relations of the wrist joint are the flexor and extensor tendons by which it is surrounded, and the radial and ulnar artery.

Actions.—The movements of the wrist joint are flexion, extension, adduction, abduction, and circumduction. In these motions the articular surfaces glide upon each other.

8. Articulations between the Carpal Bones.—These are amphiarthrodial joints, with the exception of the conjoined head of the os magnum and unciforme, which is received into a cup formed by the scaphoid, semilunar, and cuneiform bone, and constitutes an anarthrosis. The ligaments are,

Dorsal,
Palmar,
Interosseous fibro-cartilage,
Anterior annular.

The dorsal ligaments are ligamentous bands, that pass

Lateral ligaments of the same articulation; the corresponding ligaments are seen in the other articulations. 14. Transverse ligament connecting the heads of the metacarpal bones of the index and middle fingers; the same ligament is seen between the other fingers. 15 Anterior and one lateral ligament of the phalangeal articulation of the thumb. 16. Anterior and lateral ligaments of the phalangeal articulations of the index finger; the anterior ligaments are removed in the other fingers.
transversely and longitudinally from bone to bone, upon the dorsal surface of the carpus.

The *palmar ligaments* are fasciculi of the same kind, but stronger than the dorsal, having the like disposition upon the palmar surface.

The *interosseous ligaments* are fibro-cartilaginous lamellae situated between the adjoining bones in each range: in the upper range they close the upper part of the spaces between the scaphoid, semilunar, and cuneiform bones; in the lower range they are stronger than in the upper, and connect the os magnum on the one side to the unciforme, on the other to the trapezoides, and leave intervals through which the synovial membrane is continued to the bases of the metacarpal bones.

The *anterior annular ligament* is a firm ligamentous band, which connects the bones of the two sides of the carpus. It is attached by one extremity to the trapezium and scaphoid, and by the other to the unciform process of the unciforme and the base of the pisiform bone, and forms an arch over the anterior surface of the carpus, beneath which the tendons of the long flexors and the median nerve pass into the palm of the hand.

The *articulation of the pisiform bone* with the cuneiform, is provided with a distinct synovial membrane, which is protected by fasciculi of ligamentous fibres, forming a kind of capsule around the joint; they are inserted into the cuneiforme, unciforme, and base of the metacarpal bone of the little finger.

**Synovial Membranes.**—There are *five* synovial membranes entering into the composition of the articulations of the carpus:

- The *first* is situated between the lower end of the ulna and the interarticular fibro-cartilage; it is called *sacciform*, from forming a sacculus between the lateral articulation of the ulna with the radius.
- The *second* is situated between the lower surface of the radius and interarticular fibro-cartilage *above*, and the first range of bones of the carpus *below*.
- The *third* is the most extensive of the synovial membranes of the wrist; it is situated between the two rows of carpal bones, and passes between the bones of the second range, to invest the carpal extremities of the four metacarpal bones of the fingers.
- The *fourth* is the synovial membrane of the articulation of the metacarpal bone of the thumb with the trapezium.
- The *fifth* is situated between the pisiform and cuneiform bone.

**Actions.**—Very little movement exists between the bones in each range, but more is permitted between the two ranges. The motions in the latter situation are those of flexion and extension.

9. The *Carpo-metacarpal Articulations.*—The second row of bones of the carpus articulates with the metacarpal bones of the four fingers by *dorsal* and *palmar* ligaments; and the metacarpal bone of the thumb with the trapezium by a true *capsular ligament*. There is also in the carpo-metacarpal articulation a thin interosseous band which passes from the ulnar edge of the os magnum to the line of junction between the third and fourth metacarpal bones.
The *dorsal ligaments* are strong fasciculi which pass from the second range of carpal to the metacarpal bones.

The *palmar ligaments* are thin fasciculi arranged upon the same plan on the palmar surface.

The *synovial membrane* is a continuation of the great synovial membrane of the two rows of carpal bones.

The *capsular ligament* of the thumb is one of the three true capsular ligaments of the skeleton; the other two being the shoulder-joint and hip-joint. The articulation has a proper *synovial membrane.*

**Fig. 68.*

The *metacarpal bones* of the four fingers are firmly connected at their bases by means of dorsal and palmar ligaments, which extend transversely from one bone to the other, and by interosseous ligaments which pass between their contiguous surfaces. Their lateral articular

facets are lined by a reflection of the great synovial membrane of the
two rows of carpal bones.

**Actions.**—The movements of the metacarpal on the carpal bones are
restricted to a slight degree of sliding motion, with the exception of
the articulation of the metacarpal bone of the thumb with the trape-
zium. In the latter articulation, the movements are, *flexion, extension,
adduction, abduction,* and *circumduction.*

10. *Metacarpo-phalangeal Articulation.*—The metacarpo-phalan-
geal articulation is a ginglymoid joint: its ligaments are four in
number,—

- Anterior,
- Two lateral,
- Transverse.

The *anterior ligaments* are thick and fibro-cartilaginous, and form
part of the articulating surface of the joints. They are grooved ex-
ternally for the lodgment of the flexor tendons, and by their internal
aspect form part of the articular surface for the head of the metacarpal
bone.

The *lateral ligaments* are strong narrow fasciculi, holding the bones
together at each side.

The *transverse ligaments* are strong ligamentous bands passing be-
tween the anterior ligaments, and connecting together the heads of
the metacarpal bones of the four fingers.

The expansion of the extensor tendon over the back of the fingers
takes the place of a posterior ligament.

**Actions.**—This articulation admits of movement in four different
directions, viz. of *flexion, extension, adduction,* and *abduction,* the two
latter being limited to a small extent. It is also capable of *circum-
duction.*

11. *Articulation of the Phalanges.*—These articulations are gingly-
moid joints: they are formed by three ligaments.

- Anterior,
- Two lateral.

The *anterior ligament* is firm and fibro-cartilaginous, and forms part
of the articular surface for the head of the phalanges. Externally it is
grooved for the reception of the flexor tendons.

The *lateral ligaments* are very strong; they are the principal bond
of connection between the bones.

The extensor tendon takes the place and performs the office of a
posterior ligament.

**Actions.**—The movements of the phalangeal joints are *flexion* and
*extension,* these movements being more extensive between the first and
second phalanges than between the second and third.

In connection with the phalanges it may be proper to examine cer-
tain fibrous bands termed *theca* or *vaginal ligaments,* which serve to
retain the tendons of the flexor muscles in their position upon the flat
surface of their bones. These fibrous bands are attached at each side to the lateral margins of the phalanges; they are thick in the inter-spaces of the joints, thin where the tendons lie upon the joints, and they are lined upon their inner surface by synovial membrane.

**LIGAMENTS OF THE LOWER EXTREMITY.**

The *ligaments of the lower extremity*, like those of the upper, may be arranged in the order of the joints to which they belong; these are, the

1. Hip joint.
2. Knee joint.
3. Articulation between the tibia and fibula.
4. Ankle joint.
5. Articulation of the tarsal bones.
6. Tarso-metatarsal articulation.
7. Metatarso-phalangeal articulation.
8. Articulation of the phalanges.

1. **Hip Joint.**—The articulation of the head of the femur with the acetabulum constitutes an enarthrosis, or ball and socket joint. The articular surfaces are the cup-shaped cavity of the acetabulum and the rounded head of the femur; the ligaments are *five* in number, viz.

   Capsular,                    Cotyloid,
   Ilio-femoral,               Transverse,
   Teres,

The *capsular ligament* (fig. 61, 8) is a strong ligamentous capsule, embracing the acetabulum superiorly, and inferiorly the neck of the femur, and connecting the two bones firmly together. It is much thicker upon the upper part of the joint, where more resistance is required, than upon the under part, and extends farther upon the neck of the femur on the anterior and superior than on the posterior and inferior side, being attached to the intertrochanteric line in front, to the base of the great trochanter above, and to the middle of the neck of the femur behind.

The *ilio-femoral ligament* (fig. 61, 9) is an accessory and radiating band, which descends obliquely from the anterior inferior spinous process of the ilium to the anterior intertrochanteric line, and strengthens the anterior portion of the capsular ligament.

The *ligamentum teres* (fig. 62, 7), triangular in shape is attached by a round apex to the depression just below the middle of the head of the femur, and by its base, which divides into two fasciculi, into the borders of the notch of the acetabulum. It is formed by a fasciculus of fibres, of variable size, surrounded by synovial membrane; sometimes the synovial membrane alone exists, or the ligament is wholly absent.
The cotyloid ligament (fig. 62, 6) is a prismoid cord of fibro-cartilage, attached around the margin of the acetabulum, and serving to deepen that cavity and protect its edges. It is much thicker upon the upper and posterior border of the acetabulum than in front, and consists of fibres which arise from the whole circumference of the brim, and interlace with each other at acute angles.

The transverse ligament is a strong fasciculus of ligamentous fibres, continuous with the cotyloid ligament, and extended across the notch in the acetabulum. It converts the notch into a foramen, through which the articular branches of the internal circumflex and obturator arteries enter the joint.

The fossa at the bottom of the acetabulum is filled by a mass of fat, covered by synovial membrane, which serves as an elastic cushion to the head of the bone during its movements. This was considered by Havers as the synovial gland.

The synovial membrane is extensive; it invests the head of the femur, and is continued around the ligamentum teres into the acetabulum, whence it is reflected upon the inner surface of the capsular ligament back to the head of the bone.

The muscles immediately surrounding and in contact with the hip-joint are, in front, the psoas and iliacus, which are separated from the capsular ligament by a large synovial bursa; above, the short head of the rectus, and the gluteus minimus; behind, the pyriformis, gemellus superior, obturator internus, gemellus inferior, and quadratus femoris; and to the inner side, the obturator externus and pectineus.

Actions.—The movements of the hip-joint are very extensive; they are flexion, extension, adduction, abduction, circumduction and rotation.

2. Knee Joint.—The knee is a ginglymoid articulation of large size, and is provided with numerous ligaments; they are thirteen in number.

Anterior or ligamentum patellae,
Posterior or ligamentum posticum Winslowii,
Internal lateral,
Two external lateral,
Anterior or external crucial,
Posterior or internal crucial,
Transverse,
Two coronary,
   Ligamentum mucosum, \{false.
   Ligamenta alaria,
   Two semilunar fibro-cartilages,
   Synovial membrane.

The first five are external to the articulation; the next five are internal to the articulation; the remaining three are mere folds of synovial membrane, and have no title to the name of ligaments. In addition to the ligaments, there are two fibro-cartilages, which are sometimes very erroneously considered among the ligaments; and a
synovial membrane, which is still more improperly named the *capsular ligament*.

The *anterior ligament*, or *ligamentum patellae*, is the prolongation of the tendon of the extensor muscles of the thigh downwards to the tubercle of the tibia. It is, therefore, no ligament; and, as we have before stated, that the patella is simply a sesamoid bone, developed in the tendon of the extensor muscles for the defence of the front of the knee joint, the ligamentum patellæ has no title to consideration, either as a ligament of the knee joint or as a ligament of the patella.

A small *bursa mucosa* is situated between the ligamentum patellæ, near its insertion and the front of the tibia, and another of larger size is placed between the anterior surface of the patella and the fascia lata.

The *posterior ligament*, *ligamentum posticum Winslowii*, is a broad expansion of ligamentous fibres which covers the whole of the posterior part of the joint. It is divisible into two lateral portions which invest the condyles of the femur, and a central portion which is depressed, and formed by the interlacement of fasciculi passing in different directions. The strongest of these fasciculi is that which is derived from the tendon of the semi-membranosus and passes obliquely upwards and outwards, from the posterior part of the inner tuberosity of the tibia to the external condyle. Other accessory fasciculi are given off by the tendon of the popliteus and by the heads of the gastrocnemius. The middle portion of the ligament supports the popliteal artery and vein, and is perforated by several openings for the passage of branches of the azygos articular artery, and for the nerves of the joint.

The *internal lateral ligament* is a broad and trapezoid layer of ligamentous fibres, attached above to the tubercle on the internal condyle of the femur, and below to the side of the inner tuberosity of the tibia. It is crossed at its lower part by the tendons of the inner hamstring from which it is separated by a synovial bursa, and it covers in the anterior slip of the semi-membranosus tendon and the inferior internal articular artery.

*External lateral ligaments.*—The *long* external lateral ligament is a

---

* An anterior view of the ligaments of the knee joint. 1. The tendon of the quadriceps extensor muscle of the leg. 2. The patella. 3. The anterior superior tibio-fibular ligament.
strong rounded cord, which descends from the posterior part of the tubercle upon the external condyle of the femur to the outer part of the head of the fibula. The short external lateral ligament is an irregular fasciculus situated behind the preceding, arising from the external condyle near the origin of the head of the gastrocnemius muscle, and inserted into the posterior part of the head of the fibula. It is firmly connected with the external semilunar fibro-cartilage, and appears principally intended to connect that cartilage with the fibula. The long external lateral ligament is covered in by the tendon of the biceps, and has passing beneath it the tendon of origin of the popliteus muscle, and the inferior external articular artery.

The true ligaments within the joint are the crucial, transverse, and coronary.

The anterior, or external crucial ligament, arises from the depression upon the head of the tibia in front of the spinous process, and passes upwards and backwards to be inserted into the inner surface of the outer condyle of the femur, as far as its posterior border. It is smaller than the posterior.

The posterior, or internal crucial ligament, arises from the depression upon the head of the tibia, behind the spinous process, and passes upwards and forwards to be inserted into the inner condyle of the femur. This ligament is less oblique and larger than the anterior.

The transverse ligament is a small slip of fibres which extends transversely from the external semilunar fibro-cartilage, near its anterior extremity, to the anterior convexity of the internal cartilage.

The coronary ligaments are the short fibres by which the convex borders of the semilunar cartilages are connected to the head of the tibia, and to the ligaments surrounding the joint.

The semilunar fibro-cartilages are two falciform plates of fibro-cartilage, situated around the margin of the head of the tibia, and serving to deepen the surface of articulation for the condyles of the femur. They are thick along their convex border, and thin and sharp along the concave edge.

* A posterior view of the ligaments of the knee-joint. 1. The fasciculus of the ligamentum posticum Winslowii, which is derived from, 2. the tendon of the semi-membranosus muscle; the latter is cut short. 3. The process of the tendon which spreads out in the fascia of the popliteus muscle. 4. The process which is sent inwards beneath the internal lateral ligament. 5. The posterior part of the internal lateral ligament. 6. The long external lateral ligament. 7. The short external lateral ligament. 8. The tendon of the popliteus muscle cut short. 9. The posterior superior tibio-fibular ligament.
The *internal semilunar fibro-cartilage* forms an oval cup for the reception of the internal condyle; it is connected by its convex border to the head of the tibia, and to the internal and posterior ligaments, by means of its coronary ligament; and by its two extremities is firmly implanted into the depressions in front and behind the spinous process. The *external semilunar fibro-cartilage* bounds a circular fossa for the external condyle; it is connected by its convex border with the head of the tibia, and to the external and posterior ligaments, by means of its coronary ligament; by its two extremities it is inserted into the depression between the two projections which constitute the spinous process of the tibia.

The two extremities of the external cartilage being inserted into the same fossa form almost a complete circle, and the cartilage being somewhat broader than the internal, nearly covers the articular surface of the tibia. The external semilunar fibro-cartilage besides giving off a fasciculus from its anterior border to constitute the transverse ligament, is continuous by some of its fibres with the extremity of the anterior crucial ligament; posteriorly it divides into three slips; one, a strong cord, ascends obliquely forwards and is inserted into the anterior part of the inner condyle in front of the posterior crucial ligament; another is the fasciculus of insertion into the fossa of the spinous process; and the third, of small size, is continuous with the posterior part of the anterior crucial ligament.

The *ligamentum mucosum* is a slender conical process of synovial membrane enclosing a few ligamentous fibres which proceed from the transverse ligament. It is connected, by its apex, with the anterior part of the condylode notch, and by its base is lost in the mass of fat which projects into the joint beneath the patella.

*Fig. 71.*

* The right knee joint laid open from the front, in order to shew the internal ligaments. 1. The cartilaginous surface of the lower extremity of the femur with its two condyles; the figure 5 rests upon the external; the figure 3 upon the internal condyle. 2. The anterior crucial ligament. 3. The posterior crucial ligament. 4. The transverse ligament. 5. The attachment of the ligamentum mucosum; the rest has been removed. 6. The internal semilunar fibro cartilage. 7. The external fibro-cartilage. 8. A part of the ligamentum patellae turned down. 9. The bursa, situated between the ligamentum patellae and the head of the tibia; it has been laid open. 10. The anterior superior tibio-fibular ligament. 11. The upper part of the interosseous membrane; the opening above this membrane is for the passage of the anterior tibial artery.
The alar ligaments are two fringed folds of synovial membrane, extending from the ligamentum mucosum, along the edges of the mass of fat to the sides of the patella.

The synovial membrane of the knee joint is by far the most extensive in the skeleton. It invests the cartilaginous surfaces of the condyles of the femur, of the head of tibia, and of the inner surface of the patella; it covers both surfaces of the semilunar fibro-cartilages, and is reflected upon the crucial ligaments, and upon the inner surface of the ligaments which form the circumference of the joint. On each side of the patella, it lines the tendinous aponeuroses of the vastus internus and vastus externus muscles, and forms a pouch of considerable size between the extensor tendon and the front of the femur. It also forms the folds in the interior of the joint, called "ligamentum mucosum," and "ligamenta alaria." The superior pouch of the synovial membrane is supported and raised during the movements of the limb by a small muscle, the subcrureus, which is inserted into it.

Between the ligamentum patellae and the synovial membrane is a considerable mass of fat, which presses the membrane towards the interior of the joint, and occupies the fossa between the two condyles.

* A longitudinal section of the left knee joint, shewing the reflections of its synovial membrane. 1. The cancellous structure of the lower part of the femur. 2. The tendon of the extensor muscles of the leg. 3. The patella. 4. The ligamentum patellae. 5. The cancellous structure of the head of the tibia. 6. A bursa situated between the ligamentum patellae and the head of the tibia. 7. The mass of fat projecting into the cavity of the joint below the patella. ** The synovial membrane. 8. The pouch of synovial membrane which ascends between the tendon of the extensor muscles of the leg, and the front of the lower extremity of the femur. 9. One of the alar ligaments; the other has been removed with the opposite section. 10. The ligamentum mucosum left entire; the section being made to its inner side. 11. The anterior or external crucial ligament. 12. The posterior ligament. The scheme of the synovial membrane, which is here presented to the student, is divested of all unnecessary complications. It may be traced from the sacculus (at 8), along the inner surface of the patella; then over the adipose mass (7) from which it throws off the mucous ligament (10); then over the head of the tibia, forming a sheath to the crucial ligaments; then upwards along the posterior ligament and condyles of the femur, to the sacculus whence its examination commenced.
Besides the proper ligaments of the articulation, the joint is protected on its anterior part by the fascia lata, which is thicker upon the outer than upon the inner side, by a tendinous expansion from the vastus internus, and by some scattered ligamentous fibres which are inserted into the sides of the patella.

**Actions.**—The knee-joint is one of the strongest of the articulations of the body, while at the same time it admits of the most perfect degree of movement in the directions of flexion and extension. During flexion the articular surface of the tibia glides forward on the condyles of the femur, the lateral ligaments, the posterior, and the crucial ligaments are relaxed, while the ligamentum patellae being put upon the stretch, serves to press the adipose mass into the vacuity formed in the front of the joint. In extension all the ligaments are put upon the stretch with the exception of the ligamentum patellae. When the knee is semi-flexed, a partial degree of rotation is permitted.

3. **Articulation between the Tibia and Fibula.** — The tibia and fibula are held firmly connected by means of seven ligaments, viz.

- Anterior, \{ above.
- Posterior, \{ below.
- Interosseous membrane,
- Interosseous inferior,
- Transverse.

The anterior superior ligament is a strong fasciculus of parallel fibres passing obliquely downwards and outwards from the inner tuberosity of the tibia, to the anterior surface of the head of the fibula.

The posterior superior ligament is disposed in a similar manner upon the posterior surface of the joint.

Within the articulation there is a distinct synovial membrane which is sometimes continuous with that of the knee-joint.

The interosseous membrane or superior interosseous ligament is a broad layer of aponeurotic fibres which pass obliquely downwards and outwards, from the sharp ridge on the tibia, to the inner edge of the fibula and are crossed at an acute angle by a few fibres passing in the opposite direction. The ligament is deficient above, leaving a considerable interval between the bones, through which the anterior tibial artery takes its course forwards to the anterior aspect of the leg, and near its lower third there is an opening for the anterior peroneal artery and vein.

The interosseous membrane is in relation, in front, with the tibialis anticus, extensor longus digitorum, and extensor proprius pollicis muscle, with the anterior tibial vessels and nerve, and with the anterior peroneal artery; and behind with the tibialis posticus, and flexor longus digitorum muscle, and with the posterior peroneal artery.
The *inferior interosseous ligament* consists of short and strong fibres, which hold the bones firmly together inferiorly, where they are nearly in contact. This articulation is so firm that the fibula is likely to be broken in the attempt to rupture the ligament.

The *anterior inferior ligament* is a broad band, consisting of two fasciculi of parallel fibres which pass obliquely across the anterior aspect of the articulation of the two bones at their inferior extremity, from the tibia to the fibula.

The *posterior inferior ligament* (fig. 75, 2) is a similar band upon the posterior surface of the articulation. Both ligaments project somewhat below the margin of the bones, and serve to deepen the cavity of articulation for the astragalus.

The *transverse ligament* (fig. 75, 3) is a narrow band of ligamentous fibres, continuous with the preceding, and passing transversely across the back of the ankle joint between the two malleoli.

The *synovial membrane* of the inferior tibio-fibular articulation, is a duplicature of the synovial membrane of the ankle joint reflected upwards for a short distance between the two bones.

**Actions.**—An obscure degree of movement exists between the tibia and fibula, which is principally calculated to enable the latter to resist injury by yielding for a trifling extent to the pressure exerted.

4. *Ankle-joint.*—The ankle is a ginglymoid articulation; the surfaces entering into its formation are the under surface of the tibia with its malleolus and the malleolus of the fibula, above, and the surface of the astragalus with its two lateral facets, below. The ligaments are three in number:

Anterior,
Internal lateral,
External lateral.

The *anterior ligament* is a thin membranous layer, passing from the margin of the tibia, to the astragalus in front of the articular surface. It is *in relation, in front*, with the extensor tendons of the great and lesser toes, with the tendons of the tibialis anticus and peroneus tertius, and with the anterior tibial vessels and nerve. *Posteriorly* it lies in contact with the extra-synovial adipose tissue and with the synovial membrane.

* An internal view of the ankle joint. 1. The internal malleolus of the tibia. 2, 2. Part of the astragalus; the rest is concealed by the ligaments. 3. The os calcis. 4. The scaphoid bone. 5. The internal cuneiform bone. 6. The internal lateral or deltoid ligament. 7. The anterior ligament. 8. The tendo Achillis; a small bursa is seen interposed between this tendon and the tuberosity of the os calcis.
The internal lateral or deltoid ligament is a triangular layer of fibres, attached superiorly by its apex to the internal malleolus, and inferiorly by an expanded base to the astragalus, os calcis, and scaphoid bone. Beneath the superficial layer of this ligament is a much stronger and thicker fasciculus which connects the apex of the internal malleolus with the side of the astragalus.

This internal lateral ligament is covered in and partly concealed by the tendon of the tibialis posticus, and at its posterior part is in relation with the tendon of the flexor longus digitorum, and with that of the flexor longus pollicis.

The external lateral ligament consists of three strong fasciculi, which proceed from the inner side of the external malleolus, and diverge in three different directions. The anterior fasciculus passes forwards, and is attached to the astragalus; the posterior, backwards, and is connected with the astragalus posteriorly; and the middle, longer than the other two, descends to be inserted into the outer side of the os calcis.

"It is the strong union of this bone," says Sir Astley Cooper, with the tarsal bones by means of the external lateral ligaments, "which leads to its being more frequently fractured than dislocated."

The transverse ligament of the tibia and fibula occupies the place of a posterior ligament. It is in relation, behind, with the posterior tibial vessels and nerve, and with the tendon of the tibialis posticus muscle; and in front, with the extra-synovial adipose tissue, and synovial membrane.

The Synovial membrane invests the cartilaginous surfaces of the tibia and fibula (sending a duplicature upwards between their lower ends), and the upper surface and two sides of the astragalus. It is then reflected upon the anterior and lateral ligaments, and upon the transverse ligament posteriorly.

Actions.—The movements of the ankle joint are flexion and extension only, without lateral motion.

5. Articulation of the Tarsal Bones.—The ligaments which connect the seven bones of the tarsus to each other are of three kinds,—

* An external view of the ankle joint. 1. The tibia. 2. The external malleolus of the fibula. 3, 3. The astragalus. 4. The os calcis. 5. The cuboid bone. 6. The anterior fasciculus of the external lateral ligament attached to the astragalus. 7. Its middle fasciculus, attached to the os calcis. 8. Its posterior fasciculus, attached to the astragalus. 9. The anterior ligament of the ankle.
TARSAL ARTICULATIONS.

Dorsal,
Plantar,
Interosseous.

The dorsal ligaments are small fasciculi of parallel fibres, which pass from each bone to all the neighbouring bones with which it articulates. The only dorsal ligaments deserving of particular mention are, the external and posterior calcaneo-astragaloid, which, with the interosseous ligament, complete the articulation of the astragalus with the os calcis; the superior and internal calcaneo-cuboid ligaments; and the superior astragalo-scaphoid ligament. The internal calcaneo-cuboid and the superior calcaneo-scaphoid ligament, which are closely united posteriorly in the deep groove which intervenes between the astragalus and os calcis, separate anteriorly to reach their respective bones; they form the principal bond of connection between the first and second range of the bones of the foot. It is the division of this portion of these ligaments that demands the especial attention of the surgeon in performing Chopart's operation.

The plantar ligaments have the same disposition on the plantar surface of the foot; three of them, however, are of a large size and have especial names, viz. the

Calcaneo-scaphoid,
Long calcaneo-cuboid,
Short calcaneo-cuboid.

The inferior calcaneo-scaphoid ligament is a broad and fibro-cartilaginous band of ligament, which passes forwards from the anterior, and inner border of the os calcis to the edge of the scaphoid bone. In addition to connecting the os calcis and scaphoid, it supports the astragalus, and forms part of the cavity in which the rounded head of the latter bone is received. It is lined upon its upper surface by the synovial membrane of the astragalo-scaphoid articulation.

The firm connection of the os calcis with the scaphoid bone, and the feebleness of the astragalo-scaphoid articulation are conditions favorable to the occasional dislocation of the head of the astragalus.

The long calcaneo-cuboid, or ligamentum longum plantae, is a long band of ligamentous fibres, which proceeds from the under surface of the os calcis to the rough surface on the under part of the cuboid bone,

* A posterior view of the ankle joint. 1. The lower part of the interosseous membrane. 2. The posterior inferior ligament connecting the tibia and fibula. 3. The transverse ligament. 4. The internal lateral ligament. 5. The posterior fasciculus of the external lateral ligament. 6. The middle fasciculus of the external lateral ligament. 7. The synovial membrane of the ankle joint. 8. The os calcis.
its fibres being continued onwards to the bases of the third and fourth metatarsal bones.

This ligament forms the inferior boundary of a canal in the cuboid bone, through which the tendon of the peroneus longus passes to its insertion into the base of the metatarsal bone of the great toe.

The short calcaneo-cuboid, or ligamentum breve planta, is situated nearer to the bones than the long plantar ligament, from which it is separated by adipose tissue; it is broad and extensive, and ties the under surfaces of the os calcis and cuboid bone firmly together.

The interosseous ligaments are five in number; they are short and strong ligamentous fibres situated between adjoining bones, and firmly attached to their rough surfaces. One of these, the calcaneo-astragalo-lid, is lodged in the groove between the upper surface of the os calcis, and the lower of the astragalus. It is large and very strong, consists of vertical and oblique fibres, and serves to unite the os calcis and astragalus solidly together. The second interosseous ligament, also very strong, is situated between the sides of the scaphoid and cuboid bone; while the three remaining interosseous ligaments connect strongly together the three cuneiform bones and the cuboid.

The synovial membranes of the tarsus are four in number: one, for the posterior calcaneo-astragaloid articulation; a second, for the anterior calcaneo-astragaloid and astragalo-scaphoid articulation. Occasionally an additional small synovial membrane is found in the anterior calcaneo-astragaloid joint; a third, for the calcaneo-cuboid articulation; and a fourth, the large tarsal synovial membrane for the articulations between the scaphoid and three cuneiform bones, the cuneiform bones with each other, the external cuneiform bone with the cuboid, and the two external cuneiform bones with the bases of the second and third metatarsal bones. The prolongation which reaches the metatarsal bones passes forwards between the internal and middle cuneiform bones. A small synovial membrane is sometimes met with between the contiguous surfaces of the scaphoid and cuboid bone.

Actions.—The movements permitted by the articulation between the astragalus and os calcis, are a slight degree of gliding, in the directions forwards and backwards and laterally from side to side. The movements of the second range of tarsal bones is very trifling, being greater between the scaphoid and three cuneiform bones than in the other articulations. The movements occurring between the first and second range are the most considerable; they are adduction and abduction, and, in a minor degree, flexion, which increases the arch of the foot, and extension which flattens the arch.

6. Tarso-metatarsal Articulation.—The ligaments of this articulation are,

Dorsal,
Plantar,
Interosseous.
The *dorsal ligaments* connect the metatarsal to the tarsal bones, and the metatarsal bones with each other. The precise arrangement of these ligaments is of little importance, but it may be remarked, that the base of the second metatarsal bone, articulating with the three cuneiform bones receives a ligamentous slip from each, while the rest articulating with a single tarsal bone receive only a single tarsal slip.

The *plantar ligaments* have the same disposition on the plantar surface.

The *interosseous ligaments* are situated between the bases of the metatarsal bones of the four lesser toes; and also between the bases of the second and third metatarsal bones, and the internal and external cuneiform bones.

The metatarsal bone of the second toe is implanted by its base between the internal and external cuneiform bones, and is the most strongly articulated of all the metatarsal bones. This disposition must be recollected in amputation at the tarso-metatarsal articulation.

The *synovial membranes* of this articulation are three in number: one for the metatarsal bone of the great toe; one for the second and third metatarsal bones, which is continuous with the great tarsal synovial membrane; and one for the fourth and fifth metatarsal bones.

*Actions.*—The movements of the metatarsal bones upon the tarsal, and upon each other are very slight; they are such only as contribute to the strength of the foot by permitting of a certain degree of yielding to opposing forces.

7. *Metatarso-phalangeal Articulation.*—

The ligaments of this articulation, like those of the articulation between the first phalanges and metacarpal bones of the hand, are,
Anterior or plantar,
Two lateral,
Transverse.

The anterior or plantar ligaments are thick and fibro-cartilaginous, and form part of the articulating surface of the joint.
The lateral ligaments are short and very strong, and situated on each side of the joints.
The transverse ligaments are strong bands, which pass transversely between the anterior ligaments.
The expansion of the extensor tendon supplies the place of a dorsal ligament.

Actions.—The movements of the first phalanges upon the rounded heads of the metatarsal bones, are flexion, extension, adduction and abduction.

8. Articulation of the Phalanges.—The ligaments of the phalanges are the same as those of the fingers, and have the same disposition; their actions are also similar. They are,

Anterior or plantar,
Two lateral.
CHAPTER III.

ON THE MUSCLES.

Muscles are the moving organs of the animal frame; they constitute by their size and number the great bulk of the body, upon which they bestow form and symmetry. In the limbs they are situated around the bones, which they invest and defend, while they form to some of the joints a principal protection. In the trunk they are spread out to enclose cavities, and constitute a defensive wall capable of yielding to internal pressure, and again returning to its original position.

Their colour presents the deep red which is characteristic of flesh, and their form is variously modified, to execute the varied range of movements which they are required to effect.

Muscle is composed of a number of parallel fibres placed side by side, and supported and held together by a delicate web of areolar tissue; so, that if it were possible to remove the muscular substance, we should have remaining a beautiful reticular frame-work, possessing the exact form and size of the muscle without its colour and solidity. Towards the extremity of the organ the muscular fibre ceases, and the areolar structure becomes aggregated and modified, so as to constitute those glistening fibres and cords by which the muscle is tied to the surface of bone, and which are called tendons. Almost every muscle in the body is connected with bone, either by tendinous fibres, or by an aggregation of those fibres constituting a tendon; and the union is so firm, that, under extreme violence, the bone itself rather breaks than permits of the separation of the tendon from its attachment. In the broad muscles the tendon is spread so as to form an expansion, called aponeurosis (ἐξωά, longè; ψευδον; * nervus—a nerve widely spread out).

Muscles present various modifications in the arrangement of their fibres in relation to their tendinous structure. Sometimes they are completely longitudinal, and terminate at each extremity in tendon, the entire muscle being fusiform in its shape; in other situations they are disposed like the rays of a fan, converging to a tendinous point, as the temporal, pectoral, glutei, &c., and constitute a radiate muscle. Again, they are penniform, converging like the plumes of a pen to one side of a tendon, which runs the whole length of the muscle as in the peronei; or bipenniform, converging to both sides of

* The ancients named all the white fibres of the body νυγδ; the term has since been limited to the nerves.
the tendon. In other muscles the fibres pass obliquely from the 
surface of a tendinous expansion spread out on one side, to that of an-
other extended on the opposite side, as in the semi-membranosus; or,
they are composed of penniform or bipenniform fasciculi as in the del-
toid, and constitute a compound muscle.

The nomenclature of the muscles is defective and confused, and is
generally derived from some prominent character which each muscle 
presents; thus, some are named from their situation, as the tibialis,
peroneus; others from their uses, as the flexors, extensors, adductors,
abductors, levators, tensors, &c. Some again from their form, as the 
trapezius, triangularis, deltoid, &c.; and others from their direction,
as the rectus, obliquus, transversalis, &c. Certain muscles have re-
ceived names expressive of their attachments, as the sterno-mastoid,
sterno-hyoid, &c.; and others, of their divisions, as the biceps, triceps,
digastricus, complexus, &c.

In the description of a muscle we express its attachment by the 
words "origin" and "insertion:" the term origin is generally applied to 
the more fixed or central attachment, or to the point towards which 
the motion is directed, while insertion is assigned to the more movable
point, or to that most distant from the centre; but there are many 
exceptions to this principle, and as many muscles pull equally by 
both extremities, the use of such terms must be regarded as purely 
arbitrary.

In structure, muscle is composed of bundles of fibres of variable size 
called fasciculi, which are enclosed in a cellular membranous invest-
ment or sheath, and the latter is continuous with the cellular frame-
work of the fibres. Each fasciculus is composed of a number of smaller
bundles, and these of single fibres, which, from their minute size and
independent appearance, have been distinguished by the name of ulti-
mate fibres. The ultimate fibre is found by microscopic investigation
to be itself a fasciculus (ultimate fasciculus), made up of a number of
ultimate fibrils enclosed in a delicate sheath or myolemma.* Two
kinds of ultimate muscular fibre exist in the animal economy; viz.,
that of voluntary or animal life, and that of involuntary or organic
life.

The ultimate fibre of animal life is known by its size, by its uni-
formity of calibre, and especially by the very beautiful transverse
markings which occur at short and regular distances throughout its
whole extent. It also presents other markings or striae, having a
longitudinal direction, which indicate the existence of fibrillae within

* In the summer of 1836, while engaged with Dr. Jones Quain in the exami-
nation of the animal tissues with a simple dissecting microscope, constructed
by Powell, I first saw that the ultimate fibre of muscle was invested by a proper
sheath, for which I proposed the term "Myolemma;" a term which was
adopted by Dr. Quain in the fourth edition of his "Elements of Anatomy." We
at that time believed that the transverse folding of that sheath gave rise to
the appearance of transverse striae, an opinion which subsequent examinations
proved to be incorrect. Mr. Bowman employs the term "Sarcolemma," as
synonymous with Myolemma.
its myolemma. The myolemma, or investing sheath of the ultimate fibre is thin, structureless and transparent.

According to Mr. Bowman the ultimate fibres are polygonal in shape, [fig. 77] from mutual pressure. They are also variable in their size, not merely in different classes and genera of animals and different sexes, but even in the same muscle. For example, the average diameter of the ultimate fibre in the human female is 3/17, while that of the male is 3/12, the average of both being 3/18. The largest fibres are met with in fishes, in which animals they average 3/15; the next largest are found in man, while in other classes they range in the following order: — insects 3/19; reptiles 3/9; mammals 3/17; birds 3/4.

The ultimate fibrils of animal life, according to Mr. Bowman, are beaded filaments consisting of a regular succession of segments and constrictions, the latter being narrower than the former, and the component substance probably less dense.

An ultimate fibre consists of a bundle of these fibrils, which are so disposed that all the segments and all the constrictions correspond, and in this manner give rise to the alternate light and dark lines of the transverse striae. The fibrils are connected together with very different degrees of closeness in different animals; in man they are but slightly adherent, and distinct longitudinal lines of junction may be observed between them; they also separate very easily when macerated for some time. Besides the more usual separation of the ultimate fibre into fibrils, it breaks when stretched, into transverse sections [fig. 78,] corresponding with the dark line of the striae, and consequently with the constrictions of the fibrillae. When this division occurs with the greatest

* On the Minute structure and Movements of Voluntary Muscle. By Wm. Bowman, Esq. From the Philosophical Transactions for 1840.

† Transverse section of ultimate fibres of the biceps, copied from the illustrations to Mr. Bowman's paper. In this figure the polygonal form of the fibres is seen, and their composition of ultimate fibrils.

‡ An ultimate fibre, in which the transverse splitting into discs, in the direction of the constrictions of the ultimate fibrils is seen. From Mr. Bowman's paper.
facility, the longitudinal lines are indistinct, or scarcely perceptible. "In fact," says Mr. Bowman, "the primitive fasciculus seems to consist of primitive component segments or particles, arranged so as to form, in one sense, fibrillae, and in another sense, discs; and which of these two may happen to present itself to the observer, will depend on the amount of adhesion, endways or sideways, existing between the segments. Generally, in a recent fasciculus, there are transverse striae, shewing divisions into discs, and longitudinal striae, marking its composition by fibrillae."

Mr. Bowman has observed that in the substance of the ultimate fibre there exist minute "oval or circular discs, frequently concave on one or both surfaces, and containing, somewhere near the centre, one, two, or three minute dots or granules." Occasionally they are seen to present irregularities of form, which Mr. Bowman is inclined to regard as accidental. They are situated between, and are connected with the fibrils, and are distributed in pretty equal numbers through the fibre. These corpuscles are the nuclei of the nucleated cells from which the muscular fibre was originally developed. From observing, however, that their "absolute number is far greater in the adult than in the foetus, while their number, relatively to the bulk of the fasciculi, at these two epochs, remains nearly the same," Mr. Bowman regards it as certain, that "during development, and subsequently, a further and successive deposit of corpuscles" takes place. The corpuscles are brought into view only when the muscular fibre is acted upon by a solution of "one of the milder acids, as the citric."

According to my own investigations,† the ultimate fibril of animal life is cylindrical when isolated, and probably polygonal from pressure when forming part of an ultimate fibre or fasciculus. It measures in diameter \(2\,000\frac{1}{1000}\) of an inch, and is composed of a succession of cells connected by their flat surfaces. The cells are filled with a transparent substance, which I have termed myoline. The myoline differs in density in different cells, and from this circumstance bestows a peculiarity of character on certain of the cells; for example, when a fibril in its passive state is examined, there will be seen a series of dark oblong bodies separated by light spaces of equal length; now the dark bodies are

---

* Mass of ultimate fibres from the pectoralis major of the human foetus, at nine months. These fibres have been immersed in a solution of tartaric acid, and their "numerous corpuscles, turned in various directions, some presenting nucleoli," are shewn. From Mr. Bowman's paper.

† These were made on dissections of fresh human muscle, prepared with great care by Mr. Lealand, partner of the eminent optician, Mr. Powell.
each composed of a pair of cells containing the densest form of myofibril, and are hence highly refractive while the transparent spaces are constituted by a pair of cells containing a more fluid myofibril. When the fibrils are collected together so as to form an ultimate fibre or fasciculus, the appearance of the cell is altered; those which look dark in the single fibril, that is, the most refractive, being ranged side by side, constitute the bright band; while the transparent cells of the single fibril are the shaded stria of the fibre.

When the ultimate fibril is very much stretched, the two highly refractive cells appear each to be double; while the transparent space is evidently composed of four cells.

The ultimate fibre of organic life [fig. 81, D, E] is a simple homogeneous filament, much smaller than the fibre of animal life, flat, and without transverse markings. Besides these characters there may generally be seen a dark line or several dark points in its interior, and not unfrequently the entire fibre appears enlarged at irregular distances. These appearances are due to the presence of the unobiterated nuclei of cells from which the fibre was originally developed. The fibres of organic life are collected into fasciculi of various size and are held together by dark nuclear fibres similar to those which bind the fasciculi of fibrous tissue (p. 114).

The development of muscular fibre is effected by means of the formation of nucleated cells out of an original blastema, and the conversion of those cells, by a process already described (p. 5) into the tubuli of ultimate fibres, while their contents, by a subsequent developmental action are transformed into ultimate fibrils. According

* Structure of the ultimate muscular fibril and fibre of animal life.
  A. An ultimate muscular fibril in the state of partial contraction.
  B. A similar fibril in the state of ordinary relaxation. This fibril measured

28000
doing an inch in diameter.

C. A similar fibril put upon the stretch, and measuring

\[ \frac{1}{50000} \]
doing an inch in diameter.

D. Plan of a portion of an ultimate fibre, shewing the manner in which the transverse striae are produced by the collocation of the fibrils.

Nos. 1, 1. The pair of highly-refractive cells; they form the dark parts of the single fibrils, but the bright parts of the fibre D. In the stretched fibril c, each cell has the appearance of being double. 2, 2. The pair of less refractive cells, light in the single fibrils, but forming the shaded stria in D. The transverse septum between these cells is very conspicuous; and in c two other septa are seen to exist, making the number of transparent cells four. In D, the tier of cells immediately above the dark tier is partially illuminated from the obliquity of the light.
to this view the cell membranes constitute the myolemma, and the contents of the cell are a blastema out of which new cells are formed. The disposition of these latter cells, in the production of fibrillae, is probably much more simple than has hitherto been conceived. In the muscular fibre of organic life the process would seem to stop short of the formation of fibrillae, the cells being accumulated without apparent order. The corpuscles, observed by Mr. Bowman, in fetal muscle [fig. 79] and the nodosities of organic fibre are obviously undeveloped cells and nuclei.

Muscles are divided into two great classes, voluntary and involuntary, to which may be added as an intermediate and connecting link, the muscle of the vascular system, the heart.

The voluntary, or system of animal life, is developed from the external or serous layer of the germinal membrane, and comprehends the whole of the muscles of the limbs and of the trunk. The involuntary or organic system is developed from the internal or mucous layer, and constitutes the thin muscular structure of the intestinal canal, bladder, and internal organs of generation. At the commencement of the alimentary canal in the oesophagus, and near its termination in the rectum, the muscular coat is formed by a blending of the fibres of both classes. The heart is developed from the middle, or vascular layer of the germinal membrane; and although involuntary in its action, is

* A. A muscular fibre of animal life enclosed in its myolemma; the transverse and longitudinal striae are seen.
B. An ultimate fibril of muscular fibre of animal life, according to Mr. Bowman.
C. A muscular fibre of animal life, similar to A, but more highly magnified. Its myolemma is so thin and transparent as to permit the ultimate fibrils to be seen through. The true nature of the longitudinal striae is seen in this fibre, as well as the mode of formation of the transverse striae.
D. A muscular fibre of organic life from the urinary bladder, magnified 600 times, linear measure. Two of the nuclei are seen.
E. A muscular fibre of organic life, from the stomach, magnified 600 times. The diameter of this and of the preceding fibre, midway between the nuclei, was \(\frac{1}{475}\) of an inch.
composed of ultimate fibres having the transverse striæ of the muscle of animal life.

The muscles may be arranged in conformity with the general division of the body into,—1. Those of the head and neck. 2. Those of the trunk. 3. Those of the upper extremity. 4. Those of the lower extremity.

MUSCLES OF THE HEAD AND NECK.

The muscles of the head and neck admit of a subdivision into those of the head and face, and those of the neck.

Muscles of the Head and Face.—These muscles may be divided into groups corresponding with the natural regions of the head and face; the groups are eight in number, viz.—

1. Cranial group.
2. Orbital group.
3. Ocular group.
5. Superior labial group.
6. Inferior labial group.
7. Maxillary group.
8. Auricular group.

The muscles of each of these groups may be thus arranged—

1. Cranial group.
   Occipito-frontalis.

2. Orbital group.
   Orbicularis palpebrarum,
   Corrugator supercilii,
   Tensor tarsi.

3. Ocular group.
   Levator palpebræ,
   Rectus superior,
   Rectus inferior,
   Rectus internus,
   Rectus externus,
   Obliquus superior,
   Obliquus inferior.

   Pyramidalis nasi,
   Compressor nasi,
   Dilator naris.

5. Superior labial group.
   (Orbicularis oris),
   Levator labii superioris alæque nasi,
   Levator anguli oris,
   Zygomaticus major,
   Zygomaticus minor,
   Depressor labii superioris alæque nasi.

6. Inferior labial group.
   (Orbicularis oris),
   Depressor labii inferioris,
   Depressor anguli oris,
   Levator labii inferioris.

7. Maxillary group.
   Masseter,
   Temporalis,
   Buccinator,
   Pterygoideus externus,
   Pterygoideus internus.

8. Auricular group.
   Attollens aurem,
   Attrahens aurem,
   Retrahens aurem.

* The orbicularis oris, from encircling the mouth, belongs necessarily to both the superior and inferior labial regions; it is therefore enclosed within parentheses in both.
1. Cranial group.—Occipito-frontalis. Dissection.—The occipito-frontalis is to be dissected by making a longitudinal incision along the vertex of the head, from the tubercle on the occipital bone to the root of the nose; and a second incision along the forehead and around the side of the head, to join the two extremities of the preceding. Dissect the integument and superficial fascia carefully outwards, beginning at the anterior angle of the flap, where the muscular fibres are thickest, and remove it altogether.

* The muscles of the head and face. 1. The frontal portion of the occipito-frontalis. 2. Its occipital portion. 3. Its aponeurosis. 4. The orbicularis palpebrarum, which conceals the corrugator supercilii and tensor tarsi. 5. The pyramidalis nasi. 6. The compressor nasi. 7. The orbicularis oris. 8. The levator labii superioris alaeque nasi; the adjoining fasciculus between numbers 8 and 9 is the labial portion of the muscle. 9. The levator labii superioris proprius; the lower part of the levator anguli oris is seen between the muscles 10 and 11. 10. The zygomaticus minor. 11. The zygomaticus major. 12. The depressor labii inferioris. 13. The depressor anguli oris. 14. The levator labii inferioris. 15. The superficial portion of the masseter. 16. Its deep portion. 17. The attrahens aurem. 18. The buccinator. 19. The attollens aurem. 20. The temporal fascia which covers in the temporal muscle. 21. The retrahens aurem. 22. The anterior belly of the digastricus muscle; the tendon is seen passing through its aponeurotic pulley. 23. The stylohyoid muscle pierced by the posterior belly of the digastricus. 24. The mylohyoideus muscle. 25. The upper part of the sterno-mastoid. 26. The upper part of the trapezius. The muscle between 25 and 26 is the splenius.
This dissection requires care; for the muscle is very thin, and without attention would be raised with the integument. There is no deep fascia on the face and head, nor is it required; for here the muscles are closely applied against the bones upon which they depend for support, whilst in the extremities the support is derived from the dense layer of fascia by which they are invested, and which forms for each a distinct sheath.

The Occipito-frontalis is a broad musculo-aponeurotic layer, which covers the whole of the side of the vertex of the skull, from the occiput to the eyebrow. It arises by tendinous fibres from the outer two-thirds of the superior curved line of the occipital, and from the mastoid portion of the temporal bone. Its insertion takes place by means of the blending of the fibres of its anterior portion with those of the orbicularis palpebrarum, corrugator supercilii, levator labii superioris alaeque nasi, and pyramidalis nasi. The muscle is fleshy in front over the frontal bone and behind over the occipital, the two portions being connected by a broad aponeurosis. The two muscles together with their aponeurosis cover the whole of the vertex of the skull, hence their designation galea capitis; they are loosely adherent to the pericranium, but very closely to the integument, particularly over the forehead.

Relations.—This muscle is in relation by its external surface from before backwards, with the frontal and supra-orbital vessels, the supra-orbital and facial nerve, the temporal vessels and nerve, the occipital vessels and nerves, and with the integument, to which it is very closely adherent. Its under surface is attached to the pericranium by a loose areolar tissue which admits of considerable movement.

Action.—To raise the eyebrows, thereby throwing the integument of the forehead into transverse wrinkles. Some persons have the power of moving the entire scalp upon the pericranium by means of these muscles.

2. Orbital group.—Orbicularis palpebrarum,
Corrugator supercilii,
Tensor tarsi.

Dissection.—The dissection of the face is to be effected by continuing the longitudinal incision of the vertex of the previous dissection onwards to the tip of the nose, and thence downwards to the margin of the upper lip; then carry an incision along the margin of the lip to the angle of the mouth, and transversely across the face to the angle of the lower jaw. Lastly, divide the integument in front of the external ear upwards to the transverse incision which was made for exposing the occipito-frontalis. Dissect the integument and superficial fascia carefully from the whole of the region included by these incisions, and the present with the two following groups of muscles will be brought into view.

The Orbicularis Palpebrarum is a sphincter muscle, surround-
ing the orbit and eyelids. It arises from the internal angular process of the frontal bone, from the nasal process of the superior maxillary, and from a short tendon (tendo oculi) which extends between the nasal process of the superior maxillary bone, and the inner extremities of the tarsal cartilages of the eyelids. The fibres encircle the orbit and eyelids, forming a broad and thin muscular plane, which is inserted into the lower border of the tendon of the eyelid and into the nasal process of the superior maxillary bone. Upon the eyelids the fibres are thin and pale, and possess an involuntary action. The tendon of the eyelid, in addition to its insertion into the nasal process of the superior maxillary bone, sends a process inwards which expands over the lacrimal sac, and is attached to the ridge of the lacrimal bone: this is the reflected aponeurosis of the tendon of the eyelid.

Relations.—By its superficial surface it is closely adherent to the integument from which it is separated over the eyelids by a loose areolar tissue. By its deep surface it lies in contact above with the upper border of the orbit, with the corrugator supercilii muscle, and with the frontal and supra-orbital vessels and supra-orbital nerve; below, with the lacrimal sac, with the origins of the levator labii superioris alaeque nasi, levator labii superioris proprius, zygomaticus major and minor muscles, and malar bone; and externally with the temporal fascia. Upon the eyelids it is in relation with the broad tarsal ligament and tarsal cartilages, and by its upper border gives attachment to the occipito-frontalis muscle.

The Corrugator Superficialis is a small narrow and pointed muscle, situated immediately above the orbit and beneath the upper segment of the orbicularis palpebrarum muscle. It arises from the inner extremity of the superciliary ridge, and is inserted into the under surface of the orbicularis palpebrarum at a point corresponding with the middle of the superciliary arch.

Relations.—By its superficial surface, with the pyramidalis nasi, occipito-frontalis and orbicularis palpebrarum muscle; and by its deep surface, with the supra-orbital vessels and nerve.

The Tensor Tarsi (Horner's muscle) is a thin plane of muscular fibres, about three lines in breadth and six in length. It is best dissected by separating the eyelids from the eye, and turning them over the nose without disturbing the tendon of the eyelid; then dissect away the small fold of mucous membrane called plica semilunaris, and some loose cellular tissue under which the muscle is concealed. It arises from the orbital surface of the lacrimal bone, and passing across the lacrimal sac divides into two slips, which are inserted into the lacrimal canals as far as the puncta.

Actions.—The palpebral portion of the orbicularis acts involuntarily in closing the lids, and from the greater curve of the upper lid, upon that principally. The entire muscle acts as a sphincter, drawing at

* W. E. Horner, M.D. Professor of Anatomy in the University of Pennsylvania. The notice of this muscle is contained in a work published in Philadelphia in 1827, entitled "Lessons in Practical Anatomy."
the same time, by means of its osseous attachment, the integument and lids inwards towards the nose. The corrugatores superciliorum draw the eyebrows downwards and inwards, and produce the vertical wrinkles of the forehead. The tensor tarsi, or lachrymal muscle, draws the extremities of the lachrymal canals inwards, so as to place the puncta in the best position for receiving the tears. It serves also to keep the lids in relation with the surface of the eye, and compresses the lachrymal sac. Dr. Horner is acquainted with two persons who have the voluntary power of drawing the lids inwards by these muscles so as to bury the puncta in the angle of the eye.

3. Ocular group.—Levator palpebræ, Rectus superior, Rectus inferior, Rectus internus, Rectus externus, Obliquus superior, Obliquus inferior.

Dissection.—To open the orbit (the calvarium and brain having been removed) the frontal bone must be sawn through at the inner extremity of the orbital ridge; and, externally, at its outer extremity. The roof of the orbit may then be comminuted by a few light blows with the hammer; a process easily accomplished, on account of the

* The muscles of the eyeball; the view is taken from the outer side of the right orbit. 1. A small fragment of the sphenoid bone around the entrance of the optic nerve into the orbit. 2. The optic nerve. 3. The globe of the eye. 4. The levator palpebræ muscle. 5. The superior oblique muscle. 6. Its cartilaginous pulley. 7. Its reflected tendon. 8. The inferior oblique muscle, the small square knob at its commencement is a piece of its bony origin broken off. 9. The superior rectus. 10. The internal rectus almost concealed by the optic nerve. 11. Part of the external rectus, shewing its two heads of origin. 12. The extremity of the external rectus at its insertion; the intermediate portion of the muscle having been removed. 13. The inferior rectus. 14. The tunica albuginea, formed by the expansion of the tendons of the four recti.
thinness of the orbital plate of the frontal bone and lesser wing of the
sphenoid. The superciliary portion of the orbit may now be driven
forwards by a smart blow, and the external angular process and ex-
ternal wall of the orbit outwards in the same manner; the broken
fragments of the roof of the orbit should then be removed. By this
means the periosteum will be exposed unbroken and undisturbed.
Remove the periosteum from the whole of the upper surface of the
exposed orbit, and examine the parts beneath.

The **Levator Palpebrae** is a long, thin, and triangular muscle;
situated in the upper part of the orbit on the middle line; it arises
from the upper margin of the optic foramen, and from the fibrous
sheath of the optic nerve, and is inserted into the upper border of the
superior tarsal cartilage.

*Relations.*—By its *upper surface* with the fourth nerve, the supra-
orbital nerve and artery, the periosteum of the orbit, and in front with
the inner surface of the broad tarsal ligament. By its *under surface*
it rests upon the superior rectus muscle, and the globe of the eye; it
receives its nerve and artery by this aspect, and in front is covered
for a short distance by the conjunctiva.

The **Rectus Superior** (attollens) arises from the upper margin of
the optic foramen, and from the fibrous sheath of the optic nerve, and
is inserted into the upper surface of the globe of the eye at a point
somewhat more than three lines from the margin of the cornea.

*Relations.*—By its *upper surface* with the levator palpebrae muscle;
by the *under surface* with the optic nerve, the ophthalmic artery and
nasal nerve, from which it is separated by a layer of fascia and by
the adipose tissue of the orbit, and in front with the globe of the eye,
the tendon of the superior oblique muscle being interposed.

The **Rectus Inferior** (depressor) arises from the inferior margin
of the optic foramen by a tendon (ligament of Zinn) which is common
to it, the internal and the external rectus, and from the fibrous sheath
of the optic nerve; it is inserted into the inferior surface of the globe
of the eye at a little more than two lines from the margin of the
cornea.

*Relations.*—By its *upper surface* with the optic nerve, the inferior
oblique branch of the third nerve, the adipose tissue of the orbit, and
the under surface of the globe of the eye. By its *under surface* with
the periosteum of the floor of the orbit, and with the inferior oblique
muscle.

The **Rectus Internus** (adductor), the thickest and shortest of
the straight muscles, arises from the common tendon, and from the
fibrous sheath of the optic nerve; and is inserted into the inner sur-
face of the globe of the eye at two lines from the margin of the
cornea.

*Relations.*—By its *internal surface* with the optic nerve, the adipose
tissue of the orbit and the eyeball. By its *outer surface* with the pe-
riosteum of the orbit; and by its *upper border* with the anterior and
posterior ethmoidal vessels, the nasal and supra-trochlear nerve.
The **Rectus Externus** (abductor), the longest of the straight muscles, *arises* by two distinct heads, one from the common tendon, the other with the origin of the superior rectus from the margin of the optic foramen; the nasal, third, and sixth nerves passing between its heads. It is *inserted* into the outer surface of the globe of the eye at a little more than two lines from the margin of the cornea.

**Relations.**—By its *internal surface* with the third, the nasal, the sixth, and the optic nerve, the ciliary ganglion and nerves, the ophthalmic artery and vein, the adipose tissue of the orbit, the inferior oblique muscle, and the eyeball. By its *external surface* with the periosteum of the orbit; and by the *upper border* with the lacrymal vessels and nerve and the lacrymal gland.

The recti muscles present several characters which are common to all; thus, they are thin, have each the form of an isosceles triangle, bear the same relation to the globe of the eye, and are inserted in a similar manner into the sclerotica, at about two lines from the circumference of the cornea. The points of difference relate to thickness and length; the internal rectus is the thickest and shortest, the external rectus the longest of the four, and the superior rectus the most thin. The insertion of the four recti muscles into the globe of the eye forms a tendinous expansion, which is continued as far as the margin of the cornea, and is called the tunica albuginea.

The **Obliquus Superior** (trochlearis) is a fusiform muscle *arising* from the margin of the optic foramen, and from the fibrous sheath of the optic nerve; it passes forwards to the pulley beneath the internal angular process of the frontal bone; its tendon is then reflected beneath the superior rectus muscle, to the outer and posterior part of the globe of the eye, where it is *inserted* into the sclerotic coat, near the entrance of the optic nerve. The tendon is surrounded by a synovial membrane, while passing through the cartilaginous pulley.

**Relations.**—By its *superior surface* with the fourth nerve, the supra-trochlear nerve, and with the periosteum of the orbit. By the *inferior surface* with the adipose tissue of the orbit, the upper border of the internal rectus and the vessels and nerves in relation with that border.

The **Obliquus Inferior**, a thin and narrow muscle, *arises* from the inner margin of the superior maxillary bone, immediately external to the lacrymal groove, and passes beneath the inferior rectus, to be *inserted* into the outer and posterior part of the eyeball, at about two lines from the entrance of the optic nerve.

**Relations.**—By its *superior surface* with the inferior rectus muscle and with the eyeball; and by the *inferior surface* with the periosteum of the floor of the orbit, and the external rectus muscle.

According to Mr. Ferrall* the muscles of the orbit are separated from the globe of the eyeball and from the structures immediately surrounding the optic nerve, by a distinct fascia, which is continuous

* In a paper read before the Royal Society, on the 10th of June, 1841.
with the broad tarsal ligament and with the tarsal cartilages. This fascia the author terms, the *tunica vaginalis oculi,* it is pierced anteriorly for the passage of the six orbital muscles, by six openings through which the tendons of the muscles play as through pulleys. The use assigned to it by Mr. Ferrall is to protect the eyeball from the pressure of its muscles during their action. By means of this structure the recti muscles are enabled to impress a rotatory movement upon the eyeball; and in animals provided with a retractor muscle, they also act as antagonists to its action.

**Actions.**—The levator palpebrae raises the upper eyelid. The four recti, acting singly, pull the eyeball in the four directions; upwards, downwards, inwards, and outwards. Acting by pairs, they carry the eyeball in the diagonal of these directions, viz. upwards and inwards, upwards and outwards, downwards and inwards, or downwards and outwards. Acting all together, they directly retract the globe within the orbit. The superior oblique muscle, acting alone, rolls the globe inwards and forwards, and carries the pupil outwards and downwards to the lower and outer angle of the orbit. The inferior oblique, acting alone, rolls the globe outwards and backwards, and carries the pupil outwards and upwards to the upper and outer angle of the eye. Both muscles acting together, draw the eyeball forwards, and give the pupil that slight degree of eversion which enables it to admit the largest field of vision.

The **Pyramidalis Nasi** is a small pyramidal slip of muscular fibres sent downwards upon the bridge of the nose by the occipitofrontalis. It is inserted into the tendinous expansion of the compressores nasi.

**Relations.**—By its upper surface with the integument; by its under surface with the periosteum of the frontal and nasal bone. Its outer border corresponds with the edge of the orbicularis palpebrarum, and its inner border with its fellow, from which it is separated by a slight interval.

The **Compressor Nasi** is a thin and triangular muscle; it arises by its apex from the canine fossa of the superior maxillary bone, and spreads out upon the side of the nose into a thin tendinous expansion, which is continuous across its ridge with the muscle of the opposite side.

**Relations.**—By its superficial surface with the levator labii superioris proprius, the levator labii superioris alaeque nasi, and the integument; by its deep surface with the superior maxillary and nasal bone, and with the alar and lateral cartilages of the nose.

* This fascia was first described by Mr. Dalrymple in his work on the "Anatomy of the Human Eye." 1834.
The *Dilatator Naris* is a thin and indistinct muscular apparatus expanded upon the ala of the nostril, and consisting of an anterior and a posterior slip. The anterior slip (levator proprius alae nasi anterior) extends between the lateral and alar cartilage at about midway between the tip and the attached margin of the nose. The posterior slip (levator proprius alae nasi posterior) is attached above to the margin of the nasal process of the superior maxillary bone, and below to the small cartilages of the ala nasi. These muscles are difficult of dissection from the close adherence of the integument to the nasal cartilages.

**Actions.—** The *pyramidalis nasi*, as a point of attachment of the occipito-frontalis, assists that muscle in its action: it also draws down the inner angle of the eyebrow, and by its insertion fixes the aponeurosis of the compressores nasi. The compressores nasi appear to act in expanding rather than in compressing the nares; hence probably the compressed state of the nares from paralysis of these muscles in the last moments of life, or in compression of the brain. The use of the dilatator naris is expressed in its name.

5. *Superior Labial Group.* — *Orbicularis oris,*

*Levator labii superioris alaeque nasi,*
*Levator labii superioris proprius,*
*Levator anguli oris,*
*Zygomaticus major,*
*Zygomaticus minor,*
*Depressor labii superioris alaeque nasi.*

The *Orbicularis Oris* is a sphincter muscle, completely surrounding the mouth, and possessing consequently neither origin nor insertion. It is composed of two thick semicircular planes of fibres, which embrace the rima of the mouth, and interlace at their extremities, where they are continuous with the fibres of the buccinator, and of the other muscles connected with the angle of the mouth. The upper segment is attached by means of a small muscular fasciculus (naso-labialis) to the columna of the nose; and other fasciculi connected with both segments and attached to the maxillary bones are termed "accessorii."

**Relations.—** By its *superficial surface* with the integument of the lips with which it is closely connected. By its *deep surface* with the mucous membrane of the mouth, the labial glands and coronary arteries being interposed. By its *circumference* with the numerous muscles which move the lips, and by the inner border with the mucous membrane of the rima of the mouth.

The *Levator Labii Superioris Alaeque Nasi* is a thin triangular muscle; it *arises* from the upper part of the nasal process of the superior maxillary bone; and, becoming broader as it descends, is *inserted* by two distinct portions into the ala of the nose and upper lip.

**Relations.—** By its *superficial surface* with a part of the orbicularis
palpebrarum muscle, the facial artery, and the integument. By its deep surface with the superior maxillary bone, compressor nasi, alar cartilage, and with a muscular fasciculus attached only to the bone, and thence called musculus anomalous.

The **Levator Labii Superioris Proprius** is a thin quadrilateral muscle: it arises from the lower border of the orbit, and passing obliquely downwards and inwards, is inserted into the integument of the upper lip; its deep fibres being blended with those of the orbicularis.

**Relations.**—By its superficial surface with the lower segment of the orbicularis palpebrarum, with the facial artery, and with the integument. By its deep surface with the origins of the compressor nasi and levator anguli oris muscle, and with the infra-orbital artery and nerve.

The **Levator Anguli Oris** arises from the canine fossa of the superior maxillary bone, and passes outwards to be inserted into the angle of the mouth, intermingling its fibres with those of the orbicularis, zygomatici, and depressor anguli oris.

**Relations.**—By its superficial surface with the levator labii superioris proprius, the branches of the infra-orbital artery and nerve, and inferiorly with the integument. By its deep surface with the superior maxillary bone and buccinator muscle.

The **Zygomatic** muscles are two slender fasciculi of fibres which arise from the malar bone, and are inserted into the angle of the mouth, where they are continuous with the other muscles attached to this part. The zygomaticus minor is situated in front of the major, and is continuous at its insertion with the levator labii superioris proprius; it is not unfrequently wanting.

**Relations.**—The **zygomaticus major** muscle is in relation by its superficial surface with the lower segment of the orbicularis palpebrarum above, and the fat of the cheek and integument for the rest of its extent. By its deep surface with the malar bone, the masseter, and buccinator muscle, and the facial vessels. The **zygomaticus minor** being in front of the major, has no relation with the masseter muscle, while inferiorly it rests upon the levator anguli oris.

The **Depressor Labii Superioris Alæque Nasi** (myrtiformis) is seen by drawing upwards the upper lip, and raising the mucous membrane. It is a small oval slip of muscle, situated on each side of the frænum, arising from the incisive fossa, and passing upwards to be inserted into the upper lip and into the ala and columna of the nose. This muscle is continuous by its outer border with the edge of the compressor nasi.

**Relations.**—By its superficial surface with the mucous membrane of the mouth, the orbicularis oris and levator labii superioris alæque nasi muscle; and by its deep surface with the superior maxillary bone.

**Actions.**—The orbicularis oris produces the direct closure of the lips by means of its continuity at the angles of the mouth, with the fibres of the buccinator. When acting singly in the forcible closure of the mouth, the integument is thrown into wrinkles in consequence of its firm connection with the surface of the muscle. The levator labii
superioris alaeque nasi lifts the upper lip with the ala of the nose, and expands the opening of the nares. The depressor labii superioris alaeque nasi is the antagonist to this muscle, drawing the upper lip and ala of the nose downwards, and contracting the opening of the nares. The levator labii superioris proprius is the proper elevator of the upper lip; acting singly, it draws the lip a little to one side. The levator anguli oris lifts the angle of the mouth and draws it inwards, while the zygomatic pull it upwards and outwards, as in laughing.

6. Inferior Labial Group.—Depressor labii inferioris, Depressor anguli oris, Levator labii inferioris.

Dissection.—To dissect the inferior labial region continue the vertical section from the margin of the lower lip to the point of the chin. Then carry an incision along the margin of the lower jaw to its angle. Dissect off the integument and superficial fascia from the whole of this surface, and the muscles of the inferior labial region will be exposed.

The Depressor labii inferioris (quadratus menti) arises from the oblique line by the side of the symphysis of the lower jaw, and passing upwards and inwards is inserted into the orbicularis muscle and integument of the lower lip.

Relations.—By its superficial surface with the platysma myoides, part of the depressor anguli oris, and with the integument of the chin with which it is closely connected. By the deep surface with the levator labii inferioris, the labial glands and mucous membrane of the lower lip, and with the mental nerve and artery.

The Depressor anguli oris (triangularis oris) is a triangular plane of muscle arising by a broad base from the external oblique ridge of the lower jaw, and inserted by its apex into the angle of the mouth, where it is continuous with the levator anguli oris and zygomaticus major.

Relations.—By its superficial surface with the integument; and by its deep surface with the depressor labii inferioris, the buccinator and the branches of the mental nerve and artery.

The Levator labii inferioris (levator menti) is a small conical slip of muscle arising from the incisive fossa of the lower jaw, and inserted into the integument of the chin. It is in relation with the mucous membrane of the mouth, with its fellow, and with the depressor labii inferioris.

Actions.—The depressor labii inferioris draws the lower lip directly downwards, and at the same time a little outwards. The depressor anguli oris, from the radiate direction of its fibres, will pull the angle of the mouth either downwards and inwards, or downwards and outwards, and be expressive of grief; or acting with the levator anguli oris and zygomaticus major, it will draw the angle of the mouth directly backwards. The levator labii inferioris raises and protrudes the integument of the chin.
7. **Maxillary group.**—M aester,
   Temporalis,
   Buccinator,
   Pterygoideus externus,
   Pterygoideus internus.

**Dissection.**—The masseter has been already exposed by the preceding dissection.

The **Masseter** (μασσάεως, to chew,) is a short, thick and sometimes quadrilateral muscle, composed of two planes of fibres, superficial and deep. The **superficial layer** arises by a strong aponeurosis from the tuberosity of the superior maxillary bone, the lower border of the malar bone and zygoma, and passes backwards to be inserted into the ramus and angle of the inferior maxilla. The **deep layer** arises from the posterior part of the zygoma, and passes forwards, to be inserted into the upper half of the ramus. This muscle is tendinous and muscular in its structure.

**Relations.**—By its external surface with the zygomaticus major and risorius Santorini muscle, the parotid gland and Stenon’s duct, the transverse facial artery, the pes anserinus and the integument. By its **internal surface** with the temporal muscle, the buccinator, from which it is separated by a mass of fat, and with the ramus of the lower jaw. By its posterior border with the parotid gland; and by the anterior border with the facial artery and vein.

**Dissection.**—Make an incision along the upper border of the zygoma, for the purpose of separating the temporal fascia from its attachment. Then saw through the zygomatic process of the malar bone, and through the root of the zygoma, near to the meatus auditorius. Draw down the zygoma, and with it the origin of the masseter, and dissect the latter muscle away from the ramus and angle of the inferior maxilla. Now remove the temporal fascia from the rest of its attachment, and the whole of the temporal muscle will be exposed.

The **Temporalis** is a broad and radiating muscle occupying a considerable extent of the side of the head and filling the temporal fossa. It is covered in by a very dense fascia (temporal fascia) which is attached along the temporal ridge on the side of the skull, extending from the external angular process of the frontal bone to the mastoid portion of the temporal; inferiorly, it is connected to the upper border of the zygoma. The muscle arises by tendinous fibres from the whole length of the temporal ridge, and by muscular fibres from the temporal fascia and entire surface of the temporal fossa. Its fibres converge to a strong and narrow tendon, which is inserted into the apex of the coronoid process, and for some way down upon its inner surface.

**Relations.**—By its external surface with the temporal fascia, which separates it from the attollens and attrahens aurem muscle, the temporal vessels and nerves; and with the zygoma and masseter. By its internal surface with the bones forming the temporal fossa, the exter-
nal pterygoid muscle, a part of the buccinator, and the internal maxillary artery with its deep temporal branches.

By sawing through the coronoid process near to its base, and pulling it upwards, together with the temporal muscle, which may be dissected from the fossa, we obtain a view of the entire extent of the buccinator and of the external pterygoid muscle.

The Buccinator (buccina, a trumpet), the trumpeter’s muscle, arises from the alveolar process of the superior maxillary and from the external oblique line of the inferior maxillary bone, as far forward as the second bicuspid tooth, and from the pterygo-maxillary ligament. This ligament is the raphé of union between the buccinator and superior constrictor muscle, and is attached by one extremity to the hamular process of the internal pterygoid plate, and by the other to the extremity of the molar ridge. The fibres of the muscle converge towards the angle of the mouth where they cross each other, the superior being continuous with the inferior segment of the orbicularis oris, and the inferior with the superior segment. The muscle is invested externally by a thin fascia.

Relations.—By its external surface, posteriorly with a large and rounded mass of fat, which separates the muscle from the ramus of the lower jaw, the temporal, and the masseter; anteriorly with the risorius Santorini, the zygomatici, the levator anguli oris, and the depressor anguli oris. It is also in relation with a part of Stenon’s duct which pierces it opposite the second molar tooth of the upper jaw, with the transverse facial artery, the branches of the facial and buccal nerve, and the facial artery and vein. By its internal surface with the buccal glands and mucous membrane of the mouth.

The External Pterygoid is a short and thick muscle, broader at its origin than at its insertion. It arises by two heads, one from the pterygoid ridge on the greater ala of the sphenoid; the other from the external pterygoid plate and tuberosity of the palate bone. The fibres pass backwards to be inserted into the neck of the lower jaw and the interarticular fibro-cartilage. The internal maxillary artery frequently passes between the two heads of this muscle.

Relations.—By its external surface with the ramus of the lower jaw, the temporal muscle, and the internal maxillary artery; by its internal surface with the internal pterygoid muscle, internal lateral ligament of the lower jaw, arteria meningea media, and inferior maxillary nerve; and by its upper border with the muscular branches of the inferior maxillary nerve; the internal maxillary artery passes between the two heads of this muscle, and its lower origin is pierced by the buccal nerve.

The external pterygoid muscle must now be removed, the ramus of the lower jaw sawn through its lower third, and the head of the bone dislocated from its socket and withdrawn, for the purpose of seeing the pterygoideus internus.

The Internal Pterygoid is a thick quadrangular muscle. It arises from the pterygoid fossa and descends obliquely backwards, to be inserted into the ramus and angle of the lower jaw: it resembles
the masseter in appearance and direction, and was named by Winslow the internal masseter.

**Relations.**—By its external surface with the external pterygoid, the inferior maxillary nerve and its branches, the internal maxillary artery and branches, the internal lateral ligament, and the ramus of the lower jaw. By its internal surface with the tensor palati, superior constrictor and fascia of the pharynx, and by its posterior border with the parotid gland.

*Fig. 84.*

**Actions.**—The maxillary muscles are the active agents in mastication, and form an apparatus beautifully fitted for that office. The buccinator circumscribes the cavity of the mouth, and with the aid of the tongue keeps the food under the immediate pressure of the teeth. By means of its connection with the superior constrictor, it shortens the cavity of the pharynx, from before backwards, and becomes an important auxiliary in deglutition. The temporal, the masseter, and the internal pterygoid are the bruising muscles, drawing the lower jaw against the upper with great force. The two latter by the obliquity of their direction, assist the external pterygoid in grinding the food by carrying the lower jaw forward upon the upper; the jaw being brought back again by the deep portion of the masseter and posterior fibres of the temporal. The whole of these muscles, acting in succession, produce a rotatory movement of the teeth upon each other, which, with the direct action of the lower jaw against the upper, effects the proper mastication of the food.

8. **Auricular Group.**—Attollens aurem, Attrahens aurem, Retrahens aurem.

* The two pterygoid muscles. The zygomatic arch and the greater part of the ramus of the lower jaw have been removed in order to bring these muscles into view. 1. The sphenoid origin of the external pterygoid muscle. 2. Its pterygoid origin. 3. The internal pterygoid muscle.
Dissection.—The three small muscles of the ear may be exposed by removing a square of integument from around the auricula. This operation must be performed with care, otherwise the muscles, which are extremely thin, will be raised with the superficial fascia. They are best dissected by commencing with their tendons, and thence proceeding in the course of their radiating fibres.

The Attollens aurem (superior auris), the largest of the three, is a thin triangular plane of muscular fibres arising from the edge of the aponeurosis of the occipito-frontalis, and inserted into the upper part of the concha.

It is in relation by its external surface with the integument, and by the internal with the temporal aponeurosis.

The Attrahens aurem (anterior auris), also triangular, arises from the edge of the aponeurosis of the occipito-frontalis, and is inserted into the anterior part of the helix, covering in the anterior and posterior temporal arteries.

It is in relation by its external surface with the integument; and by the internal with the temporal aponeurosis and with the temporal artery and veins.

The Retrahens aurem (posterior auris), arises by three or four muscular slips from the mastoid process. They are inserted into the posterior surface of the concha.

It is in relation by its external surface with the integument, and by its internal surface with the mastoid portion of the temporal bone.

Actions.—The muscles of the auricular region possess but little action in man; they are the analogues of important muscles in brutes. Their use is sufficiently explained in their names.

MUSCLES OF THE NECK.

The muscles of the neck may be arranged into eight groups corresponding with the natural divisions of the region; they are the—

1. Superficial group.
2. Depressors of the os hyoides and larynx,
3. Elevators of the os hyoides and larynx.
4. Lingual group.
5. Pharyngeal group.
7. Prævertebral group.
8. Proper muscles of the larynx.

And each of these groups consists of the following muscles:—viz.

1. Superficial Group.
   Platysma-myoides,
   Sterno-cleido-mastoideus.

2. Depressors of the os hyoides and larynx,
   Sterno-hyoiodeus,
   Sterno-thyroideus,
   Thyro-hyoiodeus,
   Omo-hyoiodeus.
3. Elevators of the os hyoides and larynx.

Digastricus,
Stylo-hyoides,
Mylo-hyoides,
Genio-hyoides,
Genio-hyo-glossus.

4. Muscles of the Tongue.

Genio-hyoglossus,
Hyoglossus,
Lingualis,
Stylo-glossus,
Palato-glossus.

5. Muscles of the Pharynx.

Constrictor inferior,
Constrictor medius,
Constrictor superior,
Stylo-pharyngeus,
Palato-pharyngeus.

Levator palati,
Tensor palati,
Azigos uvulae,
Palato-glossus,
Palato-pharyngeus.

7. Prevertebral Group.

Rectus anticus major,
Rectus anticus minor,
Scalenus anticus,
Scalenus posticus,
Longus colli.

Crico-thyroideus,
Crico-arytaenoideus, posticus,
Crico-arytaenoideus, lateralis,
Thyro-arytaenoideus,
Arytaenoideus.

Dissection.—The dissection of the neck should be commenced by making an incision along the middle line of its fore part from the chin to the sternum, and bounding it superiorly and inferiorly by two transverse incisions; the superior one being carried along the margin of the lower jaw, and across the mastoid process to the tubercle on the occipital bone, the inferior one along the clavicle to the acromion process. The square flap of integument thus included should be turned back from the entire side of the neck, which brings into view the superficial fascia, and on the removal of a thin layer of superficial fascia the platysma myoides will be exposed.

The Platysma myoides (πλάτυς, μύς έιδος, broad muscle-like lamella), is a thin plane of muscular fibres, situated between the two layers of the superficial cervical fascia; it arises from the integument over the pectoralis major and deltoid muscles, and passes obliquely upwards and inwards along the side of the neck to be inserted into the side of the chin, oblique line of the lower jaw, the angle of the mouth, and into the cellular tissue of the face. The most anterior fibres are continuous beneath the chin, with the muscle of the opposite side; the next interlace with the depressor anguli oris, and depressor labii inferioris, and the most posterior fibres are disposed in a transverse direction across the side of the face, arising in the cellular tissue covering the parotid gland, and inserted into the angle of the mouth, constituting the risorius Santorini. The entire muscle is analogous to the cutaneous muscle of brutes, the panniculus carnosus.

Relations.—By its external surface with the integument, with which it is closely adherent below, but loosely above. By its internal surface,
below the clavicle, with the pectoralis major and deltoid; in the neck with the external jugular vein and deep cervical fascia; on the face, with the parotid gland, the masseter, the facial artery and vein, the buccinator, the depressor anguli oris, and the depressor labii inferioris.

On raising the platysma throughout its whole extent, the sternomastoid is brought into view.

The **Sterno-cleido-mastoid** is the large oblique muscle of the neck, and is situated between two layers of the deep cervical fascia. It arises as implied in its name from the sternum and clavicle (στένος), and passes obliquely upwards and backwards to be inserted into the

*Fig. 85.*
mastoid process and into the superior curved line of the occipital bone. The sternal portion arises by a rounded tendon, increases in breadth as it ascends, and spreads out to a considerable extent at its insertion. The clavicular portion is broad and fleshy, and separate from the sternal portion below, but becomes gradually blended with its posterior surface as it ascends.

**Relations.**—By its superficial surface with the integument, the platysma myoides, the external jugular vein, superficial branches of the anterior cervical plexus of nerves, and the anterior layer of the deep cervical fascia. By its deep surface with the deep layer of the cervical fascia; with the sterno-clavicular articulation, the sterno-hyoid, sterno-thyroid, omo-hyoid, scaleni, levator anguli scapulae, splenii, and the posterior belly of the digastric muscle; with the phrenic nerve, and the posterior, and supra-scapular artery; with the deep lymphatic glands, the sheath of the common carotid and internal jugular vein, the descendens noni nerve, the external carotid artery and its posterior branches, the commencement of the internal carotid artery; with the cervical plexus of nerves, the pneumogastric, the spinal accessory, the hypoglossal, the sympathetic and the facial nerve, and with the parotid gland. It is pierced on this aspect by the spinal accessory nerve and by the branches of the mastoid artery. The anterior border of the muscle is the posterior boundary of the great anterior triangle, the other two boundaries being the middle line of the neck in front, and the lower border of the jaw above. It is the guide to the operations for the ligature of the common carotid artery and arteria innominata, and for oesophagotomy. The posterior border is the anterior boundary of the great posterior triangle; the other two boundaries being the anterior border of the trapezius behind, and the clavicle below.

**Actions.**—The platysma produces a muscular traction on the integument of the neck, which prevents it from falling so flaccid in old persons as would be the case if the extension of the skin were the mere result of elasticity. It draws also upon the angle of the mouth, and is one of the depressors of the lower jaw. The transverse fibres draw the angle of the mouth outwards and slightly upwards. The sternomastoid muscles are the great anterior muscles of connection between the thorax and the head. Both muscles acting together bow the head directly forwards. The clavicular portions, acting more forcibly than the sternal, give stability and steadiness to the head in supporting great weights. Either muscle acting singly would draw the head towards the shoulder of the same side, and carry the face towards the opposite side.

**Second Group.**—*Depressors of the Os Hyoides and Larynx.*

- Sterno-hyoid,
- Sterno-thyroid,
- Thyro-hyoid,
- Omo-hyoid.

**Dissection.**—These muscles are brought into view by removing the
deep fascia from off the front of the neck between the two sterno-
mastoid muscles. The omo-hyoid to be seen in its whole extent re-
quires that the sterno-mastoid muscle should be divided from its origin
and turned aside.

The Sterno-hyoi deus, is a narrow riband-like muscle, arising
from the posterior surface of the first bone of the sternum and inner
extremity of the clavicle. It is inserted into the lower border and
posterior surface of the body of the os hyoides. The sterno-hyoides
are separated by a considerable interval at the root of the neck, but
approach each other as they ascend: they are frequently traversed by
a tendinous intersection.

Relations.—By its external surface with the deep cervical fascia, the
platysma myoides and sterno-mastoid muscle; by its internal surface
with the sterno-thyroid, and thyro-hyoid muscle, and the superior
thyroid artery.

The Sterno-thyroideus, broader than the preceding beneath
which it lies, arises from the posterior surface of the upper bone of
the sternum, and from the cartilage of the first rib; it is inserted
into the oblique line on the great ala of the thyroid cartilage. The
inner borders of these muscles lie in contact along the middle line,
and they are generally marked by a tendinous intersection at their
lower part.

Relations.—By its external surface with the sterno-hyoid, omo-
hyoid, and sterno-mastoid muscle; by its internal surface, with the
trachea and inferior thyroid veins, with the thyroid gland, the lower
part of the larynx, the sheath of the common carotid artery and
internal jugular vein, with the subclavian vein and vena innominata,
and on the right side with the arteria innominata. The middle thy-
roid vein lies along its inner border.

The Thyro-hyoides is the continuation upwards of the sterno-
thyroid muscle. It arises from the oblique line on the thyroid carti-
lage, and is inserted into the lower border of the body and great cornu
of the os hyoides.

Relations.—By its external surface with the sterno-hyoid and omo-
hyoid muscle; by its internal surface with the great ala of the thyroid
cartilage, the thyro-hyoidean membrane, and the superior laryngeal
artery and nerve.

The Omo-hyoides (8uos, shoulder) is a double-bellied muscle
passing obliquely across the neck from the scapula to the os hyoides;
it forms an obtuse angle behind the sterno-mastoid muscle, and is
retained in that position by means of a process of the deep cervical
fascia which is connected to the inner border of its tendon. It arises
from the upper border of the scapula, and from the transverse liga-
ment of the supra-scapular notch, and is inserted into the lower border
of the body of the os hyoides.

Relations.—By its superficial surface with the trapezius, the sub-
clavius and clavicle, the deep cervical fascia and platysma myoides,
the sterno-mastoid, and the integument. By its deep surface with the
brachial plexus, the scaleni muscles, the phrenic nerve, the sheath of the common carotid artery and jugular vein, the descendens noni nerve, the sterno-thyroid, and thyro-hyoid muscle, and the sterno-hyoid at its insertion. The scapular portion of the muscle divides the great posterior triangle into a superior or occipital triangle; and an inferior or subclavian triangle, which contains the subclavian artery and bra-chial plexus of nerves; the other two boundaries of the latter being the sterno-mastoid in front and the clavicle below. The hyoid portion of the muscle, divides the great anterior triangle into an inferior carotid triangle situated below the muscle, and into a superior triangle which lies above the muscle and is again subdivided by the digastricus into the submaxillary triangle and the superior carotid triangle. The other two boundaries of the inferior carotid triangle, are the middle line of the neck in front and the anterior border of the sterno-mastoid behind. The other boundaries of the superior carotid triangle are the posterior belly of the digastricus muscle above and the anterior border of the sterno-mastoid behind.

*Actions.*—The four muscles of this group are the depressors of the os hyoides and larynx. The three former drawing these parts downwards in the middle line, and the two omo-hyoides regulating their traction to the one or other side of the neck, according to the position of the head. The omo-hyoid muscles by means of their connection with the cervical fascia are rendered tensors of that portion of the deep cervical fascia which covers in the lower part of the neck, between the two sterno-mastoid muscles.

*Third Group.—Elevators of the Os Hyoides.*

Digastricus,
Stylo-hyoid,
Mylo-hyoid,
Genio-hyoid,
Genio-hyo-glossus.

*Dissection.*—These are best dissected by placing a high block beneath the neck, and throwing the head backwards. The integument has been already dissected away, and the removal of the cellular tissue and fat brings them clearly into view.

The Digastric *cus* (δις, twice, γαστρός belly) is a small muscle situated immediately beneath the side of the body of the lower jaw; it is fleshy at each extremity, and tendinous in the middle. It *arises* from the digastric fossa, upon the inner side of the mastoid process of the temporal bone, and is *inserted* into a depression on the inner side of the lower jaw, close to the symphysis. The middle tendon is held in connection with the body of the os hyoides by an aponeurotic loop, through which it plays as through a pulley; the loop being lubricated by a synovial membrane. A thin layer of aponeurosis is given off from the tendon of the digastricus at each side, which is connected with the body of the os hyoides and forms a strong plane of fascia.
between the anterior portions of the two muscles. This fascia is named the supra-hyoidean.

Relations.—By its superficial surface with the platysma myoides, the sterno-mastoid, the anterior fasciculus of the stylo-hyoid muscle, the parotid gland, and submaxillary gland. By its deep surface with the styloid muscles, the hyo-glossus, the mylo-hyoid muscle, the external carotid artery, the lingual and the facial arteries, the internal carotid artery, the jugular vein, and the hypoglossal nerve. The digastric muscle forms the two inferior boundaries of the submaxillary triangle, the superior boundary being the side of the body of the lower jaw. In the posterior half of the submaxillary triangle are situated the submaxillary gland and the facial artery.

The Stylo-hyoides is a small and slender muscle situated in immediate relation with the posterior belly of the digastricus muscle, being pierced by its tendon. It arises from the middle of the styloid process, and is inserted into the body of the os hyoides near the middle line.

Relations.—By its superficial surface with the posterior belly of the digastricus, the parotid gland and sub-maxillary gland; its deep relations are similar to those of the posterior belly of the digastricus.

The digastricus and stylo-hyoides must be removed from their connection with the lower jaw and os hyoides, and turned aside in order to see the next muscle.

The Mylo-hyoides (μύλον, mola, i. e. attached to the molar ridge of the lower jaw) is a broad triangular plane of muscular fibres, forming, with its fellow of the opposite side, the inferior wall or floor of the mouth. It arises from the molar ridge on the lower jaw, and proceeds obliquely inwards to be inserted into the raphe of the two muscles and into the body of the os hyoides; the raphe is sometimes deficient at its anterior part.

Relations.—By its superficial or inferior surface, with the platysma myoides, the digastricus, the supra-hyoidean fascia, the submaxillary gland and the submental artery. By its deep or superior surface, with the genio-hyoides, the genio-hyo-glossus, the hyo-glossus, the stylo-glossus, the gustatory nerve, the hypoglossal nerve, Wharton’s duct, the sublingual gland, and the mucous membrane of the floor of the mouth.

After the mylo-hyoides has been examined, it should be cut away from its origin and insertion, and completely removed. The view of the next muscles would also be greatly improved by dividing the lower jaw on the near side of the symphysis, and drawing it outwards, or by removing it altogether if the ramus have been already cut across in dissecting the internal pterygoid muscle. The tongue may then be drawn out of the mouth by means of a hook.

The Genio-hyoides (γιανον, the chin) arises from a small tubercle upon the inner side of the symphysis of the lower jaw, and is inserted into the upper part of the body of the os hyoides. It is a short and slender muscle, very closely connected with the border of the following.
Relations.—By its superficial or inferior surface, with the mylo-hyoideus; by the deep or superior surface with the lower border of the genio-hyo-glossus.

The Genio-hyo-glossus (γλῶσσα, the tongue) is a triangular muscle, narrow and pointed at its origin from the lower jaw, broad and fan-shaped at its attachment to the tongue. It arises from a tubercle immediately above that of the genio-hyoideus, and spreads out to be inserted into the whole length of the tongue, from its base to the apex, and into the body of the os hyoideus.

Relations.—By its inner surface with its fellow of the opposite side. By its outer surface with the mylo-hyoideus, the hyo-glossus, the stylo-glossus, lingualis, the sublingual gland, the lingual artery, and the hypoglossal nerve. By its upper border with the mucous membrane of the floor of the mouth, in the situation of the rænum linguae; and by the lower border with the genio-hyoideus.

Actions.—The whole of this group of muscles acts upon the os hyoideus when the lower jaw is closed, and upon the lower jaw when the os hyoideus is drawn downwards, and fixed by the depressors of the os hyoideus and larynx. The genio-hyo-glossus is, moreover, a muscle of the tongue; its action upon that organ shall be considered with the next group.

Fourth Group.—Muscles of the Tongue.

Genio-hyo-glossus,
Hyo-glossus,
Lingualis,
Stylo-glossus,
Palato-glossus.

These are already exposed by the preparation we have just made; there remains, therefore, only to dissect and examine them.

The Genio-hyo-glossus, the first of these muscles, has been described with the last group.

The Hyo-glossus is a square-shaped plane of muscle, arising from the whole length of the great cornu and from the body of the os hyoideus, and inserted between the stylo-glossus and lingualis into the side of the tongue. The direction of the fibres of that portion of the muscle which arises from the body is obliquely backwards; and that from the great cornu obliquely forwards; hence they are described by Albinus as two distinct muscles, under the names of the basio-glossus, and cerato-glossus, to which he added a third fasciculus, arising from the lesser cornu, and spreading along the side of the tongue, the chondro-glossus. The basio-glossus slightly overlaps the cerato-glossus at its upper part, and is separated from it by the transverse portion of the stylo-glossus.

Relations.—By its external surface with the digastric muscle, the stylo-hyoideus, stylo-glossus and mylo-hyoideus, with the gustatory nerve, the hypoglossal nerve, Wharton’s duct and the sublingual gland. By its internal surface with the middle constrictor of the pharynx,
the lingualis, the genio-hyo-glossus, the lingual artery, and the glosso-pharyngeal nerve.

The LINGUALIS.—The fibres of this muscle may be seen towards the apex of the tongue, issuing from the interval between the hyo-

glossus and genio-hyo-glossus; it is best examined by removing the preceding muscle. It consists of a small fasciculus of fibres, running longitudinally from the base, where it is attached to the os hyoides, to the apex of the tongue. It is in relation by its under surface with the ranine artery.

* The styloid muscles and the muscles of the tongue. 1. A portion of the temporal bone of the left side of the skull, including the styloid and mastoid processes, and the meatus auditorius externus. 2. 2. The right side of the lower jaw, divided at its symphysis; the left side having been removed. 3. The tongue. 4. The genio-hyoideus muscle. 5. The genio-hyo-glossus. 6. The hyo-glossus muscle; its basio-glossus portion. 7. Its cerato-glossus portion. 8. The anterior fibres of the lingualis issuing from between the hyo-glossus and genio-hyo-glossus. 9. The stylo-glossus muscle, with a small portion of the stylo-maxillary ligament. 10. The stylo-hyoid. 11. The stylo-pharyngeus muscle. 12. The os hyoides. 13. The thyro-hyoidean membrane. 14. The thyroid cartilage. 15. The thyro-hyoideus muscle arising from the oblique line on the thyroid cartilage. 16. The cricoid cartilage. 17. The crico-thyroidean membrane, through which the operation of laryngotomy is performed. 18. The trachea. 19. The commencement of the œsophagus.
The **Stylo-glossus** arises from the apex of the styloid process, and from the stylo-maxillary ligament; it divides upon the side of the tongue into two portions, one transverse, which passes transversely inwards between the two portions of the hyo-glossus, and is lost among the transverse fibres of the substance of the tongue, and another longitudinal, which spreads out upon the side of the tongue as far as its tip.

**Relations.**—By its *external surface* with the internal pterygoid muscle, the gustatory nerve, the parotid gland, sublingual gland, and the mucous membrane of the floor of the tongue. By its *internal surface* with the tonsil, the superior constrictor muscle of the pharynx, and the hyo-glossus muscle.

The **Palato-glossus** passes between the soft palate, and the side of the base of the tongue, forming a projection of the mucous membrane, which is called the anterior pillar of the soft palate. Its fibres are lost superiorly among the muscular fibres of the palato-pharyngeus, and inferiorly among the fibres of the stylo-glossus upon the side of the tongue. This muscle with its fellow constitutes the constrictor isthmus faucium.

**Actions**—The genio-hyo-glossus muscle effects several movements of the tongue, as might be expected from its extent. When the tongue is steadied and pointed by the other muscles, the posterior fibres of the genio-hyo-glossus would dart it from the mouth, while its anterior fibres would restore it to its original position. The whole length of the muscle acting upon the tongue, would render it concave along the middle line, and form a channel for the current of fluid towards the pharynx, as in sucking. The apex of the tongue is directed to the roof of the mouth, and rendered convex from before backwards by the linguales. The hyo-glossi, by drawing down the sides of the tongue, render it convex along the middle line. It is drawn upwards at its base by the palato-glossi, and backwards or to either side by the stylo-glossi. Thus the whole of the complicated movements of the tongue may be explained, by reasoning upon the direction of the fibres of the muscles, and their probable actions. The palato-glossi muscles assisted by the uvula, have the power of closing the fauces completely, an action which takes place in deglutition.

**Fifth Group.**—**Muscles of the Pharynx.**

- Constrictor inferior,
- Constrictor medius,
- Constrictor superior,
- Stylo-pharyngeus,
- Palato-pharyngeus.

**Dissection.**—To dissect the pharynx, the trachea and oesophagus are to be cut through at the lower part of the neck, and drawn upwards by dividing the loose cellular tissue which connects the pharynx to the vertebral column. The saw is then to be applied behind the
Constrictor Medius.—Constrictor Superior.

Styloid processes, and the base of the skull sawn through. The vessels and loose structures should be removed from the preparation, and the pharynx stuffed with tow or wool for the purpose of distending it, and rendering the muscles more easy of dissection. The pharynx is invested by a proper pharyngeal fascia.

The Constrictor Inferior, the thickest of the three muscles of this class, arises from the upper rings of the trachea, the cricoid cartilage, and the oblique line of the thyroid. Its fibres spread out and are inserted into the fibrous raphe of the middle of the pharynx, the inferior fibres being almost horizontal, and the superior oblique, and overlapping the middle constrictor.

Relations.—By its external surface with the anterior surface of the vertebral column, the longus colli, the sheath of the common carotid artery, the sterno-thyroid muscle, the thyroid gland, and some lymphatic glands. By its internal surface with the middle constrictor, the stylo-pharyngeus, the palato-pharyngeus, and the mucous membrane of the pharynx. By its lower border, near the cricoid cartilage, it is in relation with the recurrent nerve; and by the upper border with the superior laryngeal nerve. The fibres of origin of this muscle are blended with those of the sterno-hyoid, sterno-thyroid, and crico-thyroid, and it frequently forms a tendinous arch across the latter.

This muscle must be removed before the next can be examined.

The Constrictor Medius arises from the great cornu of the os hyoides, from the lesser cornu, and from the stylo-hyoidean ligament. It radiates from its origin upon the side of the pharynx, the lower fibres descending and being overlapped by the constrictor inferior, and the upper fibres ascending so as to cover in the constrictor superior. It is inserted into the raphe and by a fibrous aponeurosis into the basilar process of the occipital bone.

Relations.—By its external surface with the vertebral column, the longus colli, rectus anticus major, the carotid vessels, inferior constrictor, hyo-glossus muscle, lingual artery, pharyngeal plexus of nerves, and some lymphatic glands. By its internal surface, with the superior constrictor, stylo-pharyngeus, palato-pharyngeus, and mucous membrane of the pharynx.

The upper portion of this muscle must be turned down, to bring the whole of the superior constrictor into view; in so doing, the stylo-pharyngeus muscle will be seen passing beneath its upper border.

The Constrictor Superior is a thin and quadrilateral plane of muscular fibres arising from the extremity of the molar ridge of the lower jaw, from the pterygo-maxillary ligament, and from the lower half of the internal pterygoid plate, and inserted into the raphe and basilar process of the occipital bone. Its superior fibres are arched and leave an interval between its upper border and the basilar process which is deficient in muscular fibres, and it is overlapped inferiorly by the middle constrictor. Between the side of the pharynx and the ramus of the lower jaw is a triangular interval, the maxillo-pharyngeal
space, which is bounded on the inner side by the superior constrictor muscle; on the outer side by the internal pterygoid muscle; and behind by the rectus anticus major and vertebral column. In this space are situated the internal carotid artery, the internal jugular vein, and the glossopharyngeal, pneumogastric, spinal accessory, and hypoglossal nerve.

**Relations.**—By its external surface with the vertebral column and its muscles, behind; with the vessels and nerves contained in the maxillo-pharyngeal space laterally, the middle constrictor, stylo-pharyngeus, and tensor palati muscle. By its internal surface with the levator palati, palato-pharyngeus, tonsil, and mucous membrane of the pharynx, the pharyngeal fascia being interposed.

The **Stylo-pharyngeus** is a long and slender muscle arising from the inner side of the base of the styloid process; it descends between the superior and middle constrictor muscles, and spreads out beneath the mucous membrane of the pharynx, its inferior fibres being inserted into the posterior border of the thyroid cartilage.

**Relations.**—By its external surface with the styloglossus muscle, external carotid artery, parotid gland, and the middle constrictor. By its internal surface with the internal carotid artery, internal jugular vein, superior constrictor, palato-pharyngeus, and mucous membrane. Along its lower border is seen the glossopharyngeal nerve which crosses it, opposite the root of the tongue, to pass between the superior and middle constrictor and behind the hyo-glossus.

The **palato-pharyngeus** is described with the muscles of the soft pa-

---

*A side view of the muscles of the pharynx.* 1. The trachea. 2. The cricoid cartilage. 3. The crico-thyroid membrane. 4. The thyroid cartilage. 5. The thyro-hyoid membrane. 6. The os hyoides. 7. The stylo-hyoidian ligament. 8. The oesophagus. 9. The inferior constrictor. 10. The middle constrictor. 11. The superior constrictor. 12. The stylo-pharyngeus muscle passing down between the superior and middle constrictor. 13. The upper concave border of the superior constrictor; at this point the muscular fibres of the pharynx are deficient. 14. The pterygo-maxillary ligament. 15. The buccinator muscle. 16. The orbicularis oris. 17. The mylo-hyoides.
levator. It arises from the soft palate, and is inserted into the inner surface of the pharynx, and posterior border of the thyroid cartilage.

**Actions.**—The three constrictor muscles are important agents in deglutition; they contract upon the morsel of food as soon as it is received by the pharynx, and convey it downwards into the oesophagus. The stylo-pharyngei draw the pharynx upwards and widen it laterally. The palato-pharyngei also draw it upwards, and with the aid of the uvula close the opening of the fauces.

**Sixth Group.**—**Muscles of the soft Palate.**

- Levator palati,
- Tensor palati,
- Azygos uvulae,
- Palato-glossus,
- Palato-pharyngeus.

**Dissection.**—To examine these muscles, the pharynx must be opened from behind, and the mucous membrane carefully removed from off the posterior surface of the soft palate.

The **Levator palati** is a moderately thick muscle, arises from the extremity of the petrous bone and from the posterior and inferior aspect of the Eustachian tube, and passing down by the side of the posterior nares spreads out in the structure of the soft palate as far as the middle line.

**Relations.**—**Externally** with the tensor palati and superior constrictor muscle; **internally** and **posteriorly** with the mucous membrane of the pharynx and soft palate; and by its lower border with the palatopharyngeus.

The muscles of the soft palate. 1. A transverse section through the middle of the base of the skull, dividing the basilar process of the occipital bone in the middle line, and the petrous portion of the temporal bone at each side. 2. The vomer covered by mucous membrane and separating the two posterior nares. 3, 3. The Eustachian tubes. 4. The levator palati muscle of the left side; the right has been removed. 5. The hamular process of the internal pterygoid plate of the left side, around which the aponeurosis of the tensor palati is seen turning. 6. The pterygo-maxillary ligament. 7. The superior constrictor muscle of the left side, turned aside. 8. The azygos uvulae muscle. 9. The internal pterygoid plate. 10. The external pterygoid plate. 11. The tensor palati muscle. 12. Its aponeurosis expanding in the structure of the soft palate. 13. The external pterygoid muscle. 14. The attachments of two pairs of muscles cut short; the superior pair belong to the genio-hyo-glossi...
This muscle must be turned down from its origin on one side, and removed, and the superior constrictor dissected away from its pterygoid origin, to bring the next muscle into view.

The Tensor palati (circumflexus) is a slender and flattened muscle; it arises from the scaphoid fossa at the base of the internal pterygoid plate and from the anterior aspect of the Eustachian tube. It descends to the hamular process around which it turns, and expands into a tendinous aponeurosis, which is inserted into the transverse ridge on the horizontal portion of the palate bone, and into the raphé.

Relations.—By its external surface with the internal pterygoid muscle; by its internal surface with the levator palati, internal pterygoid plate, and superior constrictor. In the soft palate, its tendinous expansion is placed in front of the other muscles and in contact with the mucous membrane.

The Azygos uvula is not a single muscle, as might be inferred from its name, but a pair of small muscles placed side by side in the middle line of the soft palate. They arise from the spine of the palate bone, and are inserted into the uvula. By their anterior surface they are connected with the tendinous expansion of the levatores palati, and by the posterior with the mucous membrane.

The two next muscles are brought into view throughout the whole of their extent, by raising the mucous membrane from off the pillars of the soft palate at each side.

The Palato-glossus (constrictor isthmi faucium) is a small fasciculus of fibres that arises in the soft palate, and descends to be inserted into the side of the tongue. It is the projection of this small muscle, covered by mucous membrane, that forms the anterior pillar of the soft palate. It has been named constrictor isthmi faucium from a function it performs in common with the palato-pharyngeus, viz. of constricting the opening of the faucæ.

The Palato-pharyngeus forms the posterior pillar of the faucæ; it arises by an expanded fasciculus from the lower part of the soft palate, where its fibres are continuous with those of the muscle of the opposite side; and is inserted into the posterior border of the thyroid cartilage. This muscle is broad above where it forms the whole thickness of the lower half of the soft palate, narrow in the posterior pillar, and again broad and thin in the pharynx where it spreads out previously to its insertion.

Relations.—In the soft palate it is in relation with the mucous membrane both by its anterior and posterior surface; above, with the muscular layer formed by the levator palati, and below with the mucous glands situated along the margin of the arch of the palate. In

muscles; the inferior pair, to the genio-hyoid. 15. The attachment of the mylo-hyoides of one side and part of the opposite. 16. The anterior attachments of the digastric muscles. 17. The depression on the lower jaw corresponding with the submaxillary gland. The depression above the mylo-hyoides, on which the number 15 rests, corresponds with the situation of the sublingual gland.
the posterior pillar of the palate, it is surrounded for two-thirds of its extent by mucous membrane. In the pharynx, it is in relation by its outer surface with the superior and middle constrictor muscles, and by its inner surface with the mucous membrane of the pharynx, the pharyngeal fascia being interposed.

Actions.—The azygos uvula shortens the uvula. The levator palati raises the soft palate, while the tensor spreads it out laterally so as to form a septum between the pharynx and posterior nares. Taking its fixed point from below the tensor palati will dilate the Eustachian tube. The palato-glossus and pharyngeus constrict the opening of the fauces, and by drawing down the soft palate they serve to press the mass of food from the dorsum of the tongue into the pharynx.

Seventh Group.—Prævertebral Muscles.

Rectus anticus major,
Rectus anticus minor,
Scalenus anticus,
Scalenus posticus,
Longus colli.

Dissection.—These muscles have already been exposed by the removal of the face from the anterior aspect of the vertebral column; all that is further needed is the removal of the fascia, by which they are invested.

The Rectus anticus major, broad and thick above, and narrow and pointed below, arises from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebrae, and is inserted into the basilar process of the occipital bone.

Relations.—By its anterior surface with the pharynx, the internal carotid artery, internal jugular vein, superior cervical ganglion, sympathetic nerve, pneumogastric, and spinal accessory nerve. By its posterior surface with the longus colli, rectus anticus minor, and superior cervical vertebrae.

The Rectus anticus minor arises from the anterior border of the lateral mass of the atlas, and is inserted into the basilar process; its fibres being directed obliquely upwards and inwards.

Relations.—By its anterior surface with the rectus anticus major, and externally with the superior cervical ganglion of the sympathetic. By its posterior surface with the articulation of the condyle of the occipital bone with the atlas, and with the anterior occipito-atloid ligament.

The Scalenus anticus is a triangular muscle, as its name implies, situated at the root of the neck and appearing like a continuation of the rectus anticus major; it arises from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebrae, and is inserted into the tubercle upon the inner border of the first rib.

Relations.—By its anterior surface with the sterno-mastoid and
omo-hyoid muscle, with the cervicalis superficialis and posterior scapular artery, with the phrenic nerve, and with the subclavian vein, by which it is separated from the subclavius muscle and clavicle. By its posterior surface with the nerves which go to form the brachial plexus, and below with the subclavian artery. By its inner side it is separated from the longus colli by the vertebral artery. Its relations with the subclavian artery and vein are very important, the vein being before and the artery behind the muscle.\* 

The Scaleus posticus arises from the posterior tubercles of all the cervical vertebrae excepting the first. It is inserted by two fleshy fasciculi into the first and second ribs. The anterior (scaleus medius) of the two fasciculi is large, and occupies all the surface of the first rib between the groove for the subclavian artery and the tuberosity. The posterior (scaleus posticus) is small, and is attached to the second rib. Albinus and Soemerring make five scaleni.

**Relations.**—By its anterior surface with the brachial plexus and subclavian artery; posteriorly with the levator anguli scapulae, cervicalis ascendens, transversalis colli, and sacro-lumbalis; internally with the first intercostal muscle, the first rib, the inter-transverse muscles, and cervical vertebrae; and externally with the sterno-mastoid, omo-hyoid, supra-scapular and posterior scapular arteries.

\* In a subject dissected in the school of the Middlesex hospital during the winter of 1841 by Mr. Joseph Rogers, the subclavian artery of the left side was placed with the vein in front of the scaleus anticus muscle.

† The prevertebral group of muscles of the neck. 1. The rectus anticus major muscle. 2. The scaleus anticus. 3. The lower part of the longus colli of the right side; it is concealed superiorly by the rectus anticus major. 4. The rectus anticus minor. 5. The upper portion of the longus colli muscle. 6. Its lower portion; the figure rests upon the seventh cervical vertebra. 7. The scaleus posticus. 8. The rectus lateralis of the left side. 9. One of the intertransversales muscles.
The **Longus colli** is a long and flat muscle, consisting of two portions. The upper arises from the anterior tubercle of the atlas, and is inserted into the transverse processes of the third, fourth, and fifth cervical vertebrae. The lower portion arises from the bodies of the second and third, and transverse processes of the fourth and fifth, and passes down the neck, to be inserted into the bodies of the three lower cervical and three upper dorsal vertebrae. We should thus arrange these attachments in a tabular form:

<table>

</tr>
<tr>
<td></td>
<td></td>
</tr>
</tbody>
</table>

In general terms, the muscle is attached to the bodies and transverse processes of the five superior cervical vertebrae above, and to the bodies of the last three cervical and first three dorsal below.

**Relations.**—By its anterior surface with the pharynx, oesophagus, the sheath of the common carotid, internal jugular vein and pneumogastric nerve, the sympathetic nerve, inferior laryngeal nerve, and inferior thyroid artery. By its posterior surface it rests upon the cervical and upper dorsal vertebrae.

**Actions.**—The rectus anticus major and minor preserve the equilibrium of the head upon the atlas; and, acting conjointly with the longus colli, flex and rotate the head and the cervical portion of the vertebral column. The scaleni muscles, taking their fixed point from below, are flexors of the vertebral column; and, from above, elevators of the ribs, and therefore inspiratory muscles.

**Eighth Group.**—**Muscles of the Larynx.**

These muscles are described with the anatomy of the larynx, in Chapter X.

**MUSCLES OF THE TRUNK.**

The muscles of the trunk may be subdivided into four natural groups; viz.

1. Muscles of the back.
2. Muscles of the thorax.
4. Muscles of the perineum.

1. **Muscles of the back.**—The region of the back, in consequence of its extent, is common to the neck, the upper extremities, and the
abdomen. The muscles of which it is composed are numerous, and may be arranged into six layers.

**First Layer.**
Trapezius,
Latissimus dorsi.

**Second Layer.**
Levator anguli scapulae,
Rhomboideus minor,
Rhomboideus major.

**Third Layer.**
Serratus posticus superior,
Serratus posticus inferior,
Splenius capitis,
Splenius colli.

**Fourth Layer.**
(Dorsal Group.)
Sacro-lumbalis,
Longissimus dorsi,
Spinalis dorsi.
(Cervical Group.)
Cervicalis ascendens,

**Fifth Layer.**
(Dorsal Group.)
Sacro-lumbalis,
Longissimus dorsi,
Spinalis dorsi.
(Cervical Group.)
Rectus anticus major,
Rectus anticus minor,
Rectus lateralis,
Obliquus inferior,
Obliquus superior.

**Sixth Layer.**
Multifidus spine,
Levatores costarum,
Supra-spinalis,
Inter-spinales,
Inter-transversales.

**First Layer.**

Dissection.—The muscles of this layer are to be dissected by making an incision along the middle line of the back, from the tubercle on the occipital bone to the coccyx. From the upper point of this incision carry a second along the side of the neck, to the middle of the clavicle. Inferiorly, an incision must be made from the extremity of the sacrum, along the crest of the ilium, to about its middle. For convenience of dissection, a fourth may be carried from the middle of the spine to the acromion process. The integument and superficial fascia, together, are to be dissected off the muscles, in the course of their fibres, over the whole of this region.

The Trapezius muscle (trapezium, a quadrangle with unequal sides) arises from the superior curved line of the occipital bone, from the ligamentum nuchae, supra-spinous ligament, and spinous processes of the last cervical and all the dorsal vertebrae. The fibres converge from these various points, and are inserted into the scapular third of the clavicle, the acromion process, and the whole length of the upper border of the spine of the scapula. The inferior fibres become tendinous near the scapula, and glide over the triangular surface at the posterior extremity of its spine, upon a bursa mucosa. When the trapezius is dissected on both sides, the two muscles resemble a tra-
pezium, or diamond-shaped quadrangle, on the posterior part of the shoulders: hence the muscle was formerly named cucullaris (cucullus, a monk's cowl). The cervical and upper part of the dorsal portion of the muscle is tendinous at its origin, and forms, with the muscle of the opposite side, a kind of tendinous ellipse.

Relations.—By its superficial surface with the integument and superficial fascia, to which it is closely adherent by its cervical portion, loosely by its dorsal portion. By its deep surface, from above downwards, with the complexus, splenius, levator anguli scapulae, supra-spinatus, a small portion of the serratus posticus superior, rhomboideus minor, rhomboideus major, intervertebral aponeurosis which separates it from the erector spinae, and with the latissimus dorsi. The anterior border of the cervical portion of this muscle forms the posterior boundary of the posterior triangle of the neck. The clavicular insertion of the muscle sometimes advances to the middle of the clavicle, or as far as the outer border of the sterno-mastoid, and occasionally it has been seen to overlap the latter. This is a point of much importance to be borne in mind in the operation for ligature of the subclavian artery. The spinal accessory nerve passes beneath the anterior border, near to the clavicle, previously to its distribution to the muscle.

The ligamentum nuchae is a thin cellulo-fibrous layer extended from the tubercle and spine of the occipital bone, to the spinous process of the seventh cervical vertebra, where it is continuous with the supra-spinous ligament. It is connected with the spinous processes of the rest of the cervical vertebrae, with the exception of the atlas, by means of a small fibrous slip which is sent off by each. It is the analogue of an important elastic ligament in animals.

The Latissimus dorsi muscle covers the whole of the lower part of the back and loins. It arises from the spinous processes of the six inferior dorsal vertebrae, from all the lumbar and sacral spinous processes, from the posterior third of the crest of the ilium, and from the three lower ribs; the latter origin takes place by muscular slips, which indagate with the external oblique muscle of the abdomen. The fibres from this extensive origin converge as they ascend, and cross the inferior angle of the scapula; they then curve around the lower border of the teres major muscle, and terminate in a short quadrilateral tendon,* which lies in front of the tendon of the teres, and is inserted into the bicipital groove. A synovial bursa is interposed between the muscle and the lower angle of the scapula, and another between its tendon and that of the teres major. The muscle frequently receives a small fasciculus from the scapula as it crosses its inferior angle.

Relations.—By its superficial surface with the integument and superficial fascia; the latter is very dense and fibrous in the lumbar region; and with the trapezius. By its deep surface, from below up-

* A small muscular fasciculus from the pectoralis major is sometimes found connected with this tendon.
The first and second and part of the third layer of muscles of the back; the first layer being shewn upon the right, and the second on the left side. 1. The trapezius muscle. 2. The tendinous portion which, with a corresponding portion in the opposite muscle, forms the tendinous ellipse on the back of the neck. 3. The acromion process and spine of the scapula. 4. The latissimus dorsi muscle. 5. The deltoid. 6. The muscles of the dorsum of the scapula, infraspinatus, teres minor, and teres major. 7. The external oblique muscle. 8. The gluteus medius. 9. The glutei maxim. 10. The levator anguli scapula. 11. The rhomboideus minor. 12. The rhomboideus major. 13. The splenius capitis; the muscle immediately above, and overlaid by the splenius, is the complexus. 14. The splenius colli, only partially seen; the common origin of
wards, with the erector spinae, serratus posticus inferior, intercostal muscles and ribs, rhomboideus major, inferior angle of the scapula and teres major. The latissimus dorsi, with the teres major, forms the posterior border of the axilla.

**Second Layer.**

**Dissection.**—This layer is brought into view by dividing the two preceding muscles near their insertion, and turning them to the opposite side.

The *Levator anguli scapulae* arises by distinct slips, from the posterior tubercles of the transverse processes of the four upper cervical vertebrae, and is inserted into the upper angle and posterior border of the scapula, as far as the triangular smooth surface at the root of its spine.

**Relations.**—By its superficial surface with the trapezius, sternomastoid, and integument. By its deep surface with the splenius colli, transversalis colli, cervicalis ascendens, scalenus posticus, and serratus posticus superior. The tendons of origin are interposed between the attachments of the scalenus posticus in front and the splenius colli behind.

The *Rhomboideus minor* (rhombus, a parallelogram with four equal sides) is a narrow slip of muscle, detached from the rhomboideus major by a slight cellular interspace. It arises from the spinous process of the last cervical vertebra and ligamentum nuchae, and is inserted into the edge of the triangular surface, on the posterior border of the scapula.

The *Rhomboideus major* arises from the spinous processes of the four upper dorsal vertebrae and from the inter-spinous ligaments; it is inserted into the posterior border of the scapula as far as its inferior angle. The upper and middle portion of the insertion is effected by means of a tendinous band which is attached in a longitudinal direction to the posterior border of the scapula.

**Relations.**—By their superficial surface the two rhomboid muscles are in relation with the trapezius, and the rhomboideus major with the latissimus dorsi and integument. By their deep surface they cover in the serratus posticus superior, part of the erector spinae, the intercostal muscles and ribs.

the splenius is seen attached to the spinous processes below the lower border of the rhomboideus major. 15. The vertebral aponeurosis. 16. The serratus posticus inferior. 17. The supra-spinatus muscle. 18. The infra-spinatus. 19. The teres minor muscle. 20. The teres major. 21. The long head of the triceps, passing between the teres minor and major to the upper arm. 22. The serratus magnus, proceeding forwards from its origin at the base of the scapula. 23. The internal oblique muscle.
Third Layer.

Dissection.—The third layer consists of muscles which arise from the spinous processes of the vertebral column, and pass outwards. It is brought into view by dividing the levator anguli scapulæ near its insertion, and reflecting the two rhomboid muscles upwards from their insertion into the scapula. The latter muscles should now be removed.

The Serratus posticus superior is situated at the upper part of the thorax; it arises from the ligamentum nuchæ, the spinous process of the last cervical and those of the two upper dorsal vertebrae. The muscle passes obliquely downwards and outwards, and is inserted by four serrations into the upper border of the second, third, fourth, and fifth ribs.

Relations.—By its superficial surface with the trapezius, rhomboideus major and minor, and serratus magnus. By its deep surface with the splenius, the upper part of the erector spinae, the intercostal muscles and ribs.

The Serratus posticus inferior arises from the spinous processes and interspinous ligaments of the two last dorsal and two upper lumbar vertebrae, and passing obliquely upwards is inserted by four serrations into the lower border of the four lower ribs. Both muscles are constituted by a thin aponeurosis for about half their extent.

Relations.—By its superficial surface with the latissimus dorsi, its tendinous origin being inseparably connected with the aponeurosis of that muscle. By its deep surface with the aponeurosis of the obliquus internus, with which it is also closely adherent; with the erector spinae, the intercostal muscles and lower ribs. The upper border is continuous with a thin tendinous layer, the vertebral aponeurosis. The Vertebral aponeurosis is a thin membranous expansion composed of longitudinal and transverse fibres, and extending the whole length of the thoracic region. It is attached mesially to the spinous processes of the dorsal vertebrae, and externally to the angles of the ribs; superiorly it is continued upwards beneath the serratus posticus superior, with the lower border of which it is sometimes connected. It serves to bind down the erector spinae, and separate it from the superficial muscles.

The serratus posticus superior must be removed from its origin and turned outwards, to bring into view the whole extent of the splenius muscle.

The Splenius muscle is single at its origin, but divides soon after into two portions, which are destined to distinct insertions. It arises from the lower half of the ligamentum nuchæ, from the spinous process of the last cervical, and from the spinous processes and interspinous ligaments of the six upper dorsal vertebrae; it divides as it ascends the neck into the splenius capitis and colli. The splenius capitis is inserted into the rough surface of the occipital bone between the two curved lines, and into the mastoid portion of the temporal bone.
The *spleius colli* is inserted into the posterior tubercles of the transverse processes of the three or four upper cervical vertebrae.

**Relations.**—By its superficial surface with the trapezius, sternomastoid, levator anguli scapulae, rhomboideus minor and major, and serratus posticus superior. By its deep surface with the spinalis dorsi, longissimus dorsi, semi-spinalis colli, complexus, trachelo-mastoid, and transversalis colli. The tendons of insertion of the splenius colli are interposed between the insertions of the levator anguli scapulae in front, and the transversalis colli behind.

The splenii of opposite sides of the neck leave between them a triangular interval, in which the complexus is seen.

**Fourth Layer.**

**Dissection.**—The two serrati and two splenii muscles must be removed by cutting them away from their origins and insertions, to bring the fourth layer into view.

Three of these muscles, viz. sacro-lumbalis, longissimus dorsi, and spinalis dorsi, are associated under the name of erector spinae. They occupy the lumbar and dorsal portion of the back. The remaining four are situated in the cervical region.

The *Sacro-lumbalis and Longissimus dorsi arise* by a common origin from the posterior third of the crest of the ilium, from the posterior surface of the sacrum, and from the lumbar vertebrae: opposite the last rib a line of separation begins to be perceptible between the two muscles. The *sacro-lumbalis is inserted* by separate tendons into the angles of the six lower ribs. On turning the muscle a little outwards, a number of tendinous slips will be seen taking their origin from the ribs, and terminating in a muscular fasciculus, by which the sacro-lumbalis is prolonged to the upper part of the thorax. This is the *musculus accessorius ad sacro-lumbalem:* it arises from the angles of the six lower ribs, and is inserted by separate tendons into the angles of the six upper ribs.

The *longissimus dorsi is inserted* into all the ribs, between their tubercles and angles.

The *Spinalis dorsi arises* from the spinous processes of the two upper lumbar and two lower dorsal vertebrae, and is inserted into the spinous processes of all the upper dorsal vertebrae; the two muscles form an ellipse, which appears to enclose the spinous processes of all the dorsal vertebrae.

**Relations.**—The erector spinae muscle is in relation by its superficial surface (in the lumbar region) with the conjoined aponeurosis of the transversalis and internal oblique muscle, which separates it from the aponeurosis of the serratus posticus inferior, and longissimus dorsi; (in the dorsal region) with the vertebral aponeurosis, which separates it from the latissimus dorsi, trapezius, and serratus posticus superior, and with the splenius. By its deep surface (in the lumbar
region) with the multifidus spinæ, transverse processes of the lumbar vertebrae, and with the middle layer of the aponeurosis of the trans-

versalis abdominis, which separates it from the quadratus lumborum; (in the dorsal region) with the multifidus spinae, semi-spinalis dorsi, levatores costarum, intercostal muscles, and ribs as far as their angles. Internally or mesially with the multifidus spine, and semi-spinalis dorsi, which separate it from the spinous processes and arches of the vertebrae.

The two layers of aponeurosis of the transversalis abdominis, together with the spinal column in the lumbar region, and the vertebral aponeurosis with the ribs and spinal column in the dorsal region, form a complete osseo-aponeurotic sheath for the erector spinae.

The Cervicalis ascendens is the continuation of the sacro-lumbalis upwards into the neck. It arises from the angles of the four upper ribs, and is inserted by slender tendons into the posterior tubercles of the transverse processes of the four lower cervical vertebrae.

Relations.—By its superficial surface with the levator anguli scapulae; by its deep surface with the upper intercostal muscles and ribs, and with the intertransverse muscles; externally with the scalenus posticus; and internally with the transversalis colli. The tendons of insertion are interposed between the attachments of the scalenus posticus and transversalis colli.

The Transversalis colli would appear to be the continuation upwards into the neck of the longissimus dorsi; it arises from the transverse processes of the third, fourth, fifth, and sixth dorsal vertebrae, and is inserted into the posterior tubercles of the transverse processes of the four or five inferior cervical vertebrae.

Relations.—By its superficial surface with the levator anguli scapulae, splenius and longissimus dorsi. By its deep surface with the complexus, trachelo-mastoideus and vertebræ; externally with the musculus accessorius ad sacro-lumbalem, and cervicalis ascendens; internally with the trachelo-mastoideus and complexus. The tendons of insertion of this muscle are interposed between the tendons of insertion of the cervicalis ascendens on the outer side, and of origin of the trachelo-mastoid on the inner side.

The Trachelo-mastoid is likewise a continuation upwards from the longissimus dorsi. It is a very slender and delicate muscle, arising from the transverse processes of the four upper dorsal and four lower cervical vertebrae, and inserted into the mastoid process to the inner side of the digastric fossa.

Relations.—The same as those of the preceding muscle, excepting that it is interposed between the transversalis colli and the complexus. Its tendons of attachment are the most posterior of those which are connected with the posterior tubercles of the transverse processes of the cervical vertebrae.

The Complexus is a large muscle, and with the splenius forms the great bulk of the back of the neck. It crosses the direction of the splenius, arising from the transverse processes of the four upper dorsal, and from the transverse and articular processes of the four lower cervical vertebrae, and is inserted into the rough surface on the occipital
bone between the two curved lines, near the occipital spine. A large fasciculus of the complexus is so distinct from the principal mass of the muscle as to have led to its description as a separate muscle under the name of biventer cervicis. This appellation is not inappropriate for the muscle consists of a central tendon, with two fleshy bellies. The complexus is crossed in the upper part of the neck by a tendinous intersection.

Relations.—By its superficial surface with the trapezius, splenius, trachelo-mastoid, transversalis colli, and longissimus dorsi. By its deep surface with the semi-spinalis dorsi and colli, the recti and obliqui. It is separated from its fellow of the opposite side by the ligamentum nuchae, and from the semi-spinalis colli by the profunda cervicis artery and princeps cervicis branch of the occipital, and by the posterior cervical plexus of nerves.

Fifth Layer.

Dissection.—The muscles of the preceding layer are to be removed by dividing them transversely through the middle, and turning one extremity upwards, the other downwards. In this way the whole of the muscles of the fourth layer may be got rid of, and the remaining muscles of the spine brought into a state to be examined.

The semi-spinales muscles are connected with the transverse and spinous processes of the vertebrae, spanning one-half of the vertebral column; hence their name semi-spinales.

The semi-spinalis dorsi arises from the transverse processes of the six lower dorsal vertebrae, and is inserted into the spinous processes of the four upper dorsal, and two lower cervical vertebrae.

The semi-spinalis colli arises from the transverse processes of the four upper dorsal vertebrae, and is inserted into the spinous processes of the four upper cervical vertebrae, commencing with the axis.

Relations.—By their superficial surface the semi-spinales are in relation from below upwards with the spinalis dorsi, longissimus dorsi, complexus, splenius, with the profunda cervicis and princeps cervicis artery, and posterior cervical plexus of nerves. By their deep surface with the multifidus spinæ muscle.

Occipital Group.—This group of small muscles is intended for the varied movements of the cranium on the atlas, and the atlas on the axis. They are extremely pretty in appearance.

The Rectus posticus major arises from the spinous process of the axis, and is inserted into the inferior curved line of the occipital bone.

The Rectus posticus minor arises from the spinous tubercle of the atlas, and is inserted into the rough surface on the occipital bone, beneath the inferior curved line.

The Rectus lateralis is extended between the transverse process of the atlas and the occipital bone; it arises from the transverse
process of the atlas, and is inserted into the rough surface of the occipital bone, external to the condyle.

The OBLIQUUS INFERIOR arises from the spinous process of the axis, and passes obliquely outwards to be inserted into the extremity of the transverse process of the atlas.

The OBLIQUUS SUPERIOR arises from the extremity of the transverse process of the atlas, and passes obliquely inwards to be inserted into the rough surface of the occipital bone, between the curved lines.

Relations.—By their superficial surface the recti and obliqui are in relation with a strong aponeurosis which separates them from the complexus. By their deep surface with the atlas and axis, and their articulations. The rectus posticus major partly covers in the rectus minor.

The rectus lateralis is in relation by its anterior surface with the internal jugular vein, and by its posterior surface with the vertebral artery.

Sixth Layer.

Dissection.—The semi-spinales muscles must both be removed to obtain a good view of the multifidus spinæ which lies beneath them, and fills up the concavity between the spinous and transverse processes, the whole length of the vertebral column.

The MULTIFIDUS SPINA consists of a great number of fleshy fasciculi extending between the transverse and spinous processes of the vertebrae, from the sacrum to the axis. Each fasciculus arises from a transverse process, and is inserted into the spinous process of the first or second vertebra above. Some deep fasciculi of the multifidus spinæ have recently been described by Professor Theile under the name of rotatores spinæ.

Relations.—By its superficial surface with the longissimus dorsi, semi-spinalis dorsi, and semi-spinalis colli. By its deep surface with the arches and spinous processes of the vertebral column, and in the cervical region with the ligamentum nuchæ.

The LEVATORES COSTARUM, twelve in number on each side, arise from the transverse processes of the dorsal vertebrae, and pass obliquely outwards and downwards to be inserted into the rough surface between the tubercle and angle of the rib below them. The first of these muscles arises from the transverse process of the last cervical vertebra, and the last from that of the eleventh dorsal. The levatores of the inferior ribs, besides the distribution here described send a fasciculus downwards to the second rib below their origin, and consequently are inserted into two ribs.

Relations.—By their superficial surface with the longissimus dorsi and sacro-lumbalis. By their deep surface with the intercostal muscles and ribs.

The SUPRA-SPINALIS is a small and irregular muscle lying upon the spinous processes in the cervical region and composed of several fasciculi. The fasciculi arise from the inferior cervical and superior
dorsal vertebrae, and are inserted into the spinous process of the axis. From its analogy to the spinalis dorsi this muscle has been named spinalis colli. It is sometimes wanting.

The Intertransversales are small muscular slips arranged in pairs and situated between the spinous processes of the vertebrae. In the cervical region there are six pairs of these muscles, the first being placed between the axis and third vertebra, and the sixth between the last cervical and first dorsal. In the dorsal region, rudiments of these muscles are occasionally met with between the upper and lower vertebrae, but are absent in the rest. In the lumbar region there are six pairs of intertransversals, the first pair occupying the interspinous space between the last dorsal and first lumbar vertebra, and the last the space between the fifth lumbar and sacrum. They are thin and imperfectly developed. Rudimentary intertransverinals are occasionally met with between the lower part of the sacrum and the coccyx; these are the analogues of the caudal muscles of brutes; in man they have been named collectively the extensor coccygis.

The Intertransversales are small quadrilateral muscles situated between the transverse processes of the vertebrae. In the cervical region they are arranged in pairs corresponding with the double conformation of the transverse processes, the vertebral artery and anterior division of the cervical nerves lying between them. The rectus anterior minor and rectus lateralis represent the intertransversales between the atlas and cranium. In the dorsal region the anterior intertransversales are represented by the intercostal muscles, while the posterior are mere tendinous bands, muscular only between the first and last vertebrae. In the lumbar region, the anterior intertransversales are thin and occupy only part of the space between the transverse processes. Analogues of posterior intertransversales exist in the form of small muscular fasciculi (interobliqui) extended between the rudimentary posterior transverse processes of the lumbar vertebrae.

With regard to the origin and insertion of the muscles of the back, the student should be informed, that no regularity attends their attachments. At the best, a knowledge of their exact connections, even were it possible to retain it, would be but a barren information, if not absolutely injurious, as tending to exclude more valuable learning. I have therefore endeavoured to arrange a plan, by which they may be more easily recollected, by placing them in a tabular form (p. 208), that the student may see, at a single glance, the origin and insertion of each, and compare the natural grouping and similarity of attachments of the various layers. In this manner also their actions will be better comprehended, and learnt with greater facility.

Actions. — The upper fibres of the trapezius draw the shoulder upwards and backwards; the middle fibres, directly backwards; and the lower, downwards and backwards. The lower fibres also act by producing rotation of the scapula upon the chest. If the shoulder be fixed the upper fibres will flex the spine towards the corresponding side. The latissimus dorsi is a muscle of the arm, drawing it back-
wards and downwards, and at the same time rotating it inwards; if the arm be fixed, the latissimus dorsi will draw the spine to that side, and, raising the lower ribs, be an inspiratory muscle; and if both arms be fixed, the two muscles will draw the whole trunk forwards, as in climbing or walking on crutches. The levator anguli scapulae lifts the upper angle of the scapula, and with it the entire shoulder, and the rhomboidei carry the scapula and shoulder upwards and backwards.

In examining the following table, the student will observe the constant recurrence of the number four in the origin and insertion of the muscles. Sometimes the four occurs at the top or bottom of a region of the spine, and frequently includes a part of two regions, and takes two from each, as in the case of the serrati. Again, he will perceive that the muscles of the upper half of the table take their origin from spinous processes, and pass outwards to transverse, whereas the lower half arise mostly from transverse processes. To the student, then, we commit these reflections, and leave it to the peculiar tenor of his own mind to make such arrangements as will be best retained by his memory.

The serrati are respiratory muscles acting in opposition to each other, the serratus posticus superior drawing the ribs upwards, and thereby expanding the chest; and the inferior drawing the lower ribs downwards and diminishing the cavity of the chest. The former is an inspiratory, the latter an expiratory muscle. The splenius muscles of one side draw the vertebral column backwards and to one side, and rotate the head towards the corresponding shoulder. The muscles of opposite sides, acting together, will draw the head directly backwards. They are the natural antagonists of the sterno-mastoid muscles.

The sacro-lumbalis with its accessory muscle, the longissimus dorsi and spinalis dorsi, are known by the general term of erectors spinae, which sufficiently expresses their action. They keep the spine supported in the vertical position by their broad origin from below, and by means of their insertion, by distinct tendons, into the ribs and spinous processes. Being made up of a number of distinct fasciculi, which alternate in their actions, the spine is kept erect without fatigue, even when they have to counterbalance a corpulent abdominal development. The continuations upwards of these muscles into the neck preserve the steadiness and uprightness of that region. When the muscles of one side act alone, the neck is rotated upon its axis. The complexus, by being attached to the occipital bone, draws the head backwards, and counteracts the muscles on the anterior part of the neck. It assists also in the rotation of the head.

The semi-spinales and multifidus spinae muscles act directly on the vertebrae, and contribute to the general action of supporting the vertebral column erect.

The four little muscles situated between the occiput and the two first vertebrae, effect the various movements between these bones; the recti producing the antero-posterior actions, and the obliqui the rotatory motions of the atlas on the axis.

</table>
The actions of the remaining muscles of the spine, the _supra_ and _inter-spinales_ and _inter-transversales_, are expressed in their names. They approximate their attachments and assist the more powerful muscles in preserving the erect position of the body.

The _levatores costarum_ raise the posterior parts of the ribs, and are probably more serviceable in preserving the articulation of the ribs from dislocation, than in raising them in inspiration.

**MUSCLES OF THE THORAX.**

The principal muscles situated upon the thorax belong in their actions to the upper extremity, with which they will be described. They are the _pectoralis major_ and _minor_, _subclavius_ and _serratus magnus_. The true thoracic muscles are few in number, and appertain exclusively to the actions of the ribs; they are, the—

Intercostales externi,
Intercostales interni,
Triangularis sterni.

The intercostal muscles are two planes of muscular and tendinous fibres directed obliquely between the adjacent ribs and closing the intercostal spaces. They are seen partially upon the removal of the pectoral muscles, or upon the inner surface of the chest. The triangularis sterni is within the chest, and requires the removal of the anterior part of the thorax to bring it into view.

The _INTERCOSTALES EXTERNI_, eleven on each side, commence posteriorly at the tubercles of the ribs, and advance forwards to the costal cartilages where they terminate in a thin aponeurosis which is continued onwards to the sternum. Their fibres are directed obliquely downwards and inwards, pursuing the same line with those of the external oblique muscle of the abdomen. They are thicker than the internal intercostals.

The _INTERCOSTALES INTERNI_, also eleven on each side, commence anteriorly at the sternum, and extend backwards as far as the angles of the ribs, whence they are prolonged to the vertebral column by a thin aponeurosis. Their fibres are directed obliquely downwards and backwards, and correspond in direction with those of the internal oblique muscle of the abdomen. The two muscles cross each other in the direction of their fibres.

In structure the intercostal muscles consist of an admixture of muscular and tendinous fibres. They _arise_ from the two lips of the lower border of the ribs, the external from the outer lip, the internal from the inner, and are _inserted_ into the upper border.

_Relations._—The external intercostals, by their _external surface_, with the muscles which immediately invest the chest, viz. the _pectoralis major_ and _minor_, the _serratus magnus_, _serratus posticus superior_
and inferior, scalenus posticus; sacro-lumbalis, and longissimus dorsi, with their continuations, the cervicalis ascendens and transversalis colli; the levatores costarum, and the obliquus externus abdominis. By their internal surface with the internal intercostals, the intercostal vessels and nerves, and a thin aponeurosis, and posteriorly with the pleura. The internal intercostals, by their external surface with the external intercostals, and intercostal vessels and nerves; by their internal surface with the pleura costalis, the triangularis sterni and diaphragm.

Connected with the internal intercostals are a variable number of muscular fasciculi which pass from the inner surface of one rib near its middle to the next or next but one below; these are the subcostal or more correctly the intracostal muscles.

The Triangularis sterni, situated upon the inner wall of the front of the chest, arises by a thin aponeurosis from the side of the sternum, ensiform cartilage, and sternal extremities of the costal cartilages; and is inserted by fleshy digitations into the cartilages of the third, fourth, fifth, and sixth ribs, and often into that of the second.

Relations.—By its external surface with the sternum, the ensiform cartilage, the costal cartilages, internal intercostal muscles, and internal mammary vessels. By its internal surface with the pleura costalis, the areolar tissue of the anterior mediastinum and the diaphragm. The lower fibres of the triangularis sterni are continuous with those of the diaphragm.

Actions.—The intercostal muscles raise the ribs when they act from above, and depress them when they take their fixed point from below. They are, therefore, both inspiratory and expiratory muscles. The triangularis sterni draws down the costal cartilages, and is therefore an expiratory muscle.

MUSCLES OF THE ABDOMEN.

The muscles of this region are, the—

Obliquus externus (descendens),
Obliquus internus (ascendens),
Cremaster,
Transversalis,
Rectus,
Pyramidalis,
Quadratus lumborum,
Psoas parvus,
Diaphragm.

Dissection.—The dissection of the abdominal muscles is to be commenced by making three incisions:—The first, vertical, in the middle
MUSCLES OF THE ABDOMEN.

line, from over the lower part of the sternum to the pubes; the second, oblique, from the umbilicus, upwards and outwards, to the outer side of the chest, as high as the fifth or sixth rib; and the third, oblique, from the umbilicus, downwards and outwards, to the middle of the crest of the ilium. The three flaps included by these incisions should then be dissected back in the direction of the fibres of the external oblique muscle, beginning at the angle of each. The integument and superficial fascia should be dissected off together so as to expose the fibres of the muscle at once.

If the external oblique muscle be dissected on both sides, a white tendinous line will be seen along the middle of the abdomen, extending from the ensiform cartilage to the os pubis; this is the linea alba. A little external to it, on each side, two curved lines will be observed extending from the sides of the chest to the os pubis, and bounding the recti muscles: these are the lineæ semilunares. Some transverse lines, lineæ transversæ, three or four in number, connect the lineæ semilunares with the linea alba.

The External Oblique Muscle (obliquus externus abdominis descendens) is the external flat muscle of the abdomen. Its name is derived from the obliquity of its direction, and the descending course of its fibres. It arises by fleshy digitations from the external surface of the eight inferior ribs; the five upper digitations being received between corresponding processes of the serratus magnus, and the three lower of the latissimus dorsi. Soon after its origin it spreads out into a broad aponeurosis, which is inserted into the outer lip of the crest of the ilium for one half its length, the anterior superior spinous process of the ilium, spine of the os pubis, pectineal line, front of the os pubis, and linea alba.

The lower border of the aponeurosis, which is stretched between the anterior superior spinous process of the ilium and the spine of the os pubis, is rounded from being folded inwards, and forms Poupart's ligament; the insertion into the pectineal line is Gimbernat's ligament.

Just above the crest of the os pubis is the external abdominal ring, a triangular opening formed by the separation of the fibres of the aponeurosis of the external oblique. It is oblique in its direction, and corresponds with the course of the fibres of the aponeurosis. It is bounded below by the crest of the os pubis; on either side, by the borders of the aponeurosis, which are called pillars; and above by some curved fibres (inter-columnar), which originate from Poupart's ligament, and cross the upper angle of the ring, so as to give it strength. The external pillar, which is at the same time inferior from the obliquity of the opening, is inserted into the spine of the os pubis; the internal or superior pillar forms an interlacement with its fellow of the opposite side over the front of the symphysis pubis. The external abdominal ring gives passage to the spermatic cord in the male, and round ligament in the female: they are both invested in their passage through it by a thin fascia derived from the edges of the ring, and called inter-columnar fascia, or fascia spermatica.
The pouch of inguinal hernia, in passing through this opening, receives the *inter-columnar fascia*, as one of its coverings.

**Relations.**—By its *external surface* with the superficial fascia and integument, and with the cutaneous vessels and nerves, particularly the superficial epigastric and superficial circumflexa illi vessels. It is generally overlapped posteriorly by the latissimus dorsi. By its *internal surface* with the internal oblique, the lower part of the eight inferior ribs and intercostal muscles, the cremaster, the spermatic cord in the male, and the round ligament in the female. The upper border of the external oblique is continuous with the pectoralis major.

The external oblique is now to be removed by making an incision across the ribs, just below its origin, to its posterior border; and another along Poupart’s ligament and the crest of the ilium. Poupart’s ligament should be left entire, as it gives attachment to the next muscles.

The muscle may then be turned forwards towards the linea alba, or removed altogether.

The **Internal oblique muscle** (*obliquus internus abdominis, ascendens*), is the middle flat muscle of the abdomen. It *arises* from the outer half of Poupart’s ligament, from the middle of the crest of the ilium for two-thirds of its length, and by a thin aponeurosis from the spinous processes of the lumbar vertebrae. Its fibres diverge from their origin, so that those from Poupart’s ligament curve downwards, those from the anterior part of the crest of the ilium pass transversely, and the rest ascend obliquely. The muscle is *inserted* into the pectineal line and crest of the os pubis, linea alba, and lower borders of the five inferior ribs.

Along the upper three fourths of the linea semilunaris, the aponeurosis of the internal oblique separates into two lamelle, which pass one in front and the other behind the rectus muscle to the linea alba, where they are inserted; along the lower fourth, the aponeurosis passes altogether in front of the rectus without separation. The two layers, which thus enclose the rectus, form for it a partial sheath.

The lowest fibres of the internal oblique are inserted into the pectineal line of the os pubis in common with those of the transversalis muscle. Hence the tendon of this insertion is called the *conjoined tendon of the internal oblique and transversalis*. This structure corresponds with the external abdominal ring, and forms a protection to what would otherwise be a weak point in the abdomen. Sometimes the tendon is insufficient to resist the pressure from within, and becomes forced through the external ring; it then forms the distinctive covering of *direct inguinal hernia*.

The spermatic cord passes beneath the arched border of the internal oblique muscle, between it and Poupart’s ligament. During its passage some fibres are given off from the lower border of the muscle, which accompany the cord downwards to the testicle, and form loops around it: this is the cremaster muscle. In the descent of oblique inguinal hernia, which travels the same course with the spermatic cord, the cremaster muscle forms one of its coverings.
MUSCLES OF THE ABDOMEN.

Fig. 92.*

Its aponeurosis; the median line to the right of this number is the linea alba; the flexuous line to its left is the linea semilunaris; and the transverse lines above and below the number, the linea transversa. 14. Poupart's ligament. 15. The external abdominal ring; the margin above the ring is the
The CREMASTER, considered as a distinct muscle, arises from the middle of Poupart's ligament, and forms a series of loops upon the spermatic cord. A few of its fibres are inserted into the tunica vaginalis, the rest ascend along the inner side of the cord, to be inserted, with the conjoined tendon, into the pectineal line of the os pubis.

Relations.—The internal oblique is in relation by its external surface with the external oblique, latissimus dorsi, spermatic cord, and external abdominal ring. By its internal surface with the transversalis muscle, the fascia transversalis, the internal abdominal ring, and spermatic cord. By its lower and arched border with the spermatic cord, forming the upper boundary of the spermatic canal.

The cremaster is in relation by its external surface with the aponeurosis of the external oblique and inter-columnar fascia; and by its internal surface with the fascia propria of the spermatic cord.

The internal oblique muscle is to be removed by separating it from its attachments to the ribs above, and to the crest of the ilium and Poupart's ligament below. It should be divided behind by a vertical incision extending from the last rib to the crest of the ilium, as its lumbar attachment cannot at present be examined. The muscle is then to be turned forwards. Some degree of care will be required in performing this dissection from the difficulty of distinguishing between this muscle and the one beneath. A thin layer of cellular tissue is all that separates them for the greater part of their extent. Near the crest of the ilium the circumflexa ili artery ascends between the two muscles, and forms a valuable guide to their separation. Just above Poupart's ligament they are so closely connected that it is impossible to divide them.

The TRANSVERSALIS is the internal flat muscle of the abdomen; it is transverse in the direction of its fibres, as is implied in its name. It arises from the outer third of Poupart's ligament, from the internal lip of the crest of the ilium, its anterior two-thirds; from the spinous and transverse processes of the lumbar vertebrae, and from the inner surfaces of the six inferior ribs, indigating with the diaphragm. Its lower fibres curve downwards, to be inserted, with the lower fibres of the internal oblique, into the pectineal line, and form the conjoined tendon. Throughout the rest of its extent it is inserted into the crest of the os pubis and linea alba. The lower fourth of its aponeurosis superior or internal pillar; the margin below the ring, the inferior or external pillar; the curved intercolumnar fibres are seen proceeding upwards from Poupart's ligament to strengthen the ring. The numbers 14 and 15 are situated upon the fascia lata of the thigh; the opening immediately to the right of 15 is the saphenous opening. 16. The rectus muscle of the right side brought into view by the removal of the anterior segment of its sheath: * the posterior segment of its sheath with the divided edge of the anterior segment. 17. The pyramidalis muscle. 18. The internal oblique muscle. 19. The conjoined tendon of the internal oblique and transversalis descending behind Poupart's ligament to the pectineal line. 20. The arch formed between the lower curved border of the internal oblique muscle and Poupart's ligament; it is beneath this arch that the spermatic cord and hernia pass.
passes in front of the rectus to the linea alba; the upper three-fourths, with the posterior lamella of the internal oblique behind it.

The posterior aponeurosis of the transversalis divides into three la-

* A lateral view of the trunk of the body, shewing its muscles, and particularly the transversalis abdominis. 1. The costal origin of the latissimus dorsi muscle. 2. The serratus magnus. 3. The upper part of the external oblique muscle divided in the direction best calculated to shew the muscles beneath without interfering with its indigitations with the serratus magnus. 4. mellæ;—anterior, which is attached to the bases of the transverse processes of the lumbar vertebrae; middle, to the apices of the transverse processes; and posterior, to the apices of the spinous processes. The anterior and middle lamellæ enclose the quadratus lumborum muscle; and the middle and posterior, the erector spinae. The union of the posterior lamella of the transversalis with the posterior aponeurosis of the internal oblique, serratus posticus inferior, and latissimus dorsi, constitutes the lumbar fascia.

Relations.—By its external surface with the internal oblique, the internal surfaces of the lower ribs, and internal intercostal muscles. By its internal surface with the transversalis fascia, which separates it from the peritoneum, with the psoas magnus, and with the lower part of the rectus and pyramidalis. The spermatic cord and oblique inguinal hernia pass beneath the lower border, but have no direct relation with it.

To dissect the rectus muscle, its sheath should be opened by a vertical incision extending from over the cartilages of the lower ribs to the front of the os pubis. The sheath may then be dissected off and turned to either side; this is easily done excepting at the lineæ transverse, where a close adhesion subsists between the muscle and the external boundary of the sheath. The sheath contains the rectus and pyramidalis muscle.

The Rectus muscle arises by a flattened tendon from the crest of the os pubis, and is inserted into the cartilages of the fifth, sixth, and seventh ribs. It is traversed by several tendinous zig-zag intersections, called lineæ transverse. One of these is usually situated at the umbilicus, two above that point, and sometimes one below. They are vestiges of the abdominal ribs of reptiles, and very rarely extend completely through the muscle.

Relations.—By its external surface with the anterior lamella of the aponeurosis of the internal oblique, below with the aponeurosis of the transversalis, and pyramidalis. By its internal surface with the ensiform cartilage, the cartilages of the fifth, sixth, seventh, eighth and ninth ribs, with the posterior lamella of the internal oblique, the peritoneum, and the epigastric artery and veins.

The Pyramidalis muscle arises from the crest of the os pubis in front of the rectus, and is inserted into the linea alba at about midway between the umbilicus and the os pubis. It is enclosed in the same sheath with the rectus, and rests against the lower part of that muscle. This muscle is sometimes wanting.

The rectus may now be divided across the middle, and the two ends drawn aside for the purpose of examining the mode of formation of its sheath.

The sheath of the rectus is formed in front for the upper three-fourths of its extent, by the aponeurosis of the external oblique and the anterior lamella of the internal oblique, and behind by the posterior lamella of the internal oblique and the aponeurosis of the transversalis. At the commencement of the lower fourth, the posterior
wall of the sheath terminates in a thin curved margin, the aponeuroses of the three muscles passing altogether in front of the rectus.

The next two muscles can be examined only when the viscera of the abdomen are removed. To see the quadratus lumborum, it is also necessary to divide and draw aside the psoas muscle and the anterior lamella of the aponeurosis of the transversalis.

The **Quadratus Lumborum** muscle is concealed from view by the anterior lamella of the aponeurosis of the transversalis muscle, which is inserted into the bases of the transverse processes of the lumbar vertebrae. When this lamella is divided, the muscle will be seen **arising** from the last rib, and from the transverse processes of the four upper lumbar vertebrae. It is **inserted** into the crest of the ilium and ilio-lumbar ligament. If the muscle be cut across or removed, the middle lamella of the transversalis will be seen attached to the apices of the transverse processes; the quadratus being enclosed between the two lamellæ as in a sheath.

**Relations.**—Enclosed in the sheath formed by the transversalis muscle, it is in relation **in front** with the kidney, the colon, the psoas magnus, and the diaphragm. **Behind,** but also separated by its sheath, with the erector spinae.

The **Psoas Parvus arises** from the tendinous arches and intervertebral substance of the last dorsal and first lumbar vertebra, and terminates in a long slender tendon which expands inferiorly and is **inserted** into the ilio-pectineal line and eminence. The tendon is continuous by its outer border with the iliac fascia.

**Relations.**—It rests upon the psoas magnus, and is covered in by the peritoneum; superiorly it passes beneath the ligamentum arcuatum of the diaphragm. It is occasionally wanting.

**Diaphragm.**—To obtain a good view of this important inspiratory muscle, the peritoneum should be dissected from its under surface. It is the muscular septum between the thorax and abdomen, and is composed of two portions, a greater and a lesser muscle. The **greater muscle arises** from the ensiform cartilage; from the inner surfaces of the six inferior ribs, indigitating with the transversalis; and from the ligamentum arcuatum externum and internum. From these points, which form the internal circumference of the trunk, the fibres converge and are **inserted** into the central tendon.

The **ligamentum arcuatum externum** is the upper border of the anterior lamella of the aponeurosis of the transversalis: it arches across the origin of the quadratus lumborum muscle, and is attached by one extremity to the base of the transverse process of the first lumbar vertebra, and by the other to the apex and lower margin of the last rib.

The **ligamentum arcuatum internum, or proprium,** is a tendinous arch thrown across the psoas magnus muscle as it emerges from the chest. It is attached by one extremity to the base of the transverse process of the first lumbar vertebra, and by the other is continuous
DIAPHRAGM.

with the tendon of the lesser muscle opposite the body of the second.

The tendinous centre of the diaphragm is shaped like a trefoil leaf, of which the central leaflet points to the ensiform cartilage, and is the largest; the lateral leaflets, right and left, occupy the corresponding

* The under or abdominal side of the diaphragm. 1, 2, 3. The greater muscle; the figure 1 rests upon the central leaflet of the tendinous centre; the number 2 on the left or smallest leaflet; and number 3 on the right leaflet. 4 The thin fasciculus which arises from the ensiform cartilage; a small triangular space is left on either side of this fasciculus, which is closed only by the serous membranes of the abdomen and chest. 5. The ligamentum arcuatum externum of the left side. 6. The ligamentum arcuatum internum. 7. A small arched opening occasionally found, through which the lesser splanchnic nerve passes. 8. The right or larger tendon of the lesser muscle; a muscular fasciculus from this tendon curves to the left side of the greater muscle between the oesophageal and aortic openings. 9. The fourth lumbar vertebra. 10. The left or shorter tendon of the lesser muscle. 11. The aortic opening occupied by the aorta, which is cut short off. 12. A portion of the oesophagus issuing through the oesophageal opening; in this figure the oesophageal opening is tendinous at its anterior part, a structure which is not uncommon. 13. The opening for the inferior vena cava, in the tendinous centre of the diaphragm. 14. The psoas magnus muscle passing beneath the ligamentum arcuatum internum; it has been removed on the opposite side to shew the arch more distinctly. 15. The quadratus lumborum passing beneath the ligamentum arcuatum externum; this muscle has also been removed on the left side.
portions of the muscle; the right being the larger and more rounded, and the left smaller and lengthened in its form.

Between the sides of the ensiform cartilage and the cartilages of the adjoining ribs, is a small triangular space where the muscular fibres of the diaphragm are deficient. This space is closed only by peritoneum on the side of the abdomen, and by pleura within the chest. It is therefore a weak point, and a portion of the contents of the abdomen might, by violent exertion, be forced through it, producing phrenic, or diaphragmatic hernia.

The lesser muscle of the diaphragm takes its origin from the bodies of the lumbar vertebrae by two tendons. The right, larger and longer than the left, arises from the anterior surface of the bodies of the second, third, and fourth vertebrae; and the left from the side of the second and third. The tendons form two large fleshy bellies (crura), which ascend to be inserted into the central tendon. The inner fasciculi of the two crura cross each other in front of the aorta, and again diverge to surround the oesophagus, so as to present the appearance of a figure of eight. The anterior fasciculus of the decussation is formed by the right crus.

The openings in the diaphragm are three: one, quadrilateral, in the tendinous centre, at the union of the right and middle leaflets, for the passage of the inferior vena cava; a muscular opening of an elliptic shape formed by the two crura, for the transmission of the oesophagus and pneumogastric nerves; and a third, the aortic, which is formed by a tendinous arch thrown from the tendon of one crus to that of the other, beneath which pass the aorta, the right vena azygos, and thoracic duct. The great splanchnic nerves pass through openings in the lesser muscle on each side, and the lesser splanchnic nerves through the fibres which arise from the ligamentum arcuatum internum.

Relations.—By its superior surface with the pleurae, the pericardium, the heart, and the lungs. By its inferior surface with the peritoneum; on the left with the stomach and spleen; on the right with the convexity of the liver; and behind with the kidneys, the suprarenal capsules, the duodenum, and the solar plexus. By its circumference with the ribs and intercostal muscles, and with the vertebral column.

Actions.—The external oblique muscle, acting singly, would draw the thorax towards the pelvis, and twist the body to the opposite side. Both muscles, acting together, would flex the thorax directly on the pelvis. The internal oblique of one side draws the chest downwards and outwards: both together bend it directly forwards. Either transversalis muscle, acting singly, will diminish the size of the abdomen on its own side, and both together will constrict the entire cylinder of the cavity. The recti muscles, assisted by the pyramidales, flex the thorax upon the chest, and, through the medium of the linea transversae, are enabled to act when their sheath is curved inwards by the action of the transversales. The pyramidales are tensors of the linea alba. The abdominal are expiratory muscles, and the chief agents of
expulsion; by their action the foetus is expelled from the uterus, the urine from the bladder, the faeces from the rectum, the bile from the gall-bladder, the ingesta from the stomach and bowels in vomiting, and the mucous and irritating substances from the bronchial tubes, trachea, and nasal passages, during coughing and sneezing. To produce these efforts they all act together. Their violent and continued action produces hernia; and, acting spasmodically, they may occasion rupture of the viscera. The quadratus lumborum draws the last rib downwards, and is an expiratory muscle; it also serves to bend the vertebral column to one or the other side. The psoas parvus is a tensor of the iliac fascia, and, taking its fixed origin from below, it may assist in flexing the vertebral column forwards. The diaphragm is an inspiratory muscle, and the sole agent in tranquil inspiration. When in action, the muscle is drawn downwards, its plane being rendered oblique from the level of the ensiform cartilage, to that of the upper lumbar vertebra. During relaxation it is convex, and encroaches considerably on the cavity of the chest, particularly at the sides, where it corresponds with the lungs. It assists the abdominal muscles powerfully in expulsion, every act of that kind being preceded or accompanied by a deep inspiration. Spasmodic action of the diaphragm produces hiccough and sobbing, and its rapid alternation of contraction and relaxation, combined with laryngeal and facial movements, laughing and crying.

MUSCLES OF THE PERINEUM.

The muscles of the perineum are situated in the outlet of the pelvis, and consist of two groups, one of which belongs especially to the organs of generation and urethra, the other to the termination of the alimentary canal. To these may be added the only pair of muscles which is proper to the pelvis, the coccygeus. The muscles of the perineal region in the male, are the

Accelerator urinæ,
Erector penis,
Compressor urethrae,
Transversus perinei,
Sphincter ani,
Levator ani,
Coccygeus.

Dissection.—To dissect the perineum, the subject should be fixed in the position for lithotomy, that is, the hands should be bound to the soles of the feet, and the knees kept apart. An easier plan is the drawing of the feet upwards by means of a cord passed through a hook in the ceiling. Both of these plans of preparation have for their object the full exposure of the perineum. And as this is a dissection
which demands some degree of delicacy and nice manipulation, a strong light should be thrown upon the part. Having fixed the subject, and drawn the scrotum upwards by means of a string or hook, carry an incision from the base of the scrotum along the ramus of the pubes and ischium and tuberosity of the ischium, to a point parallel with the apex of the coccyx; then describe a curve over the coccyx to the same point on the opposite side, and continue the incision onwards along the opposite tuberosity, and along the ramus of the ischium and of the pubes, to the opposite side of the scrotum, where the two extremities may be connected by a transverse incision. This incision will completely surround the perineum, following very nearly the outline of its boundaries. Now let the student dissect off the integument carefully from the whole of the included space, and he will expose the fatty cellular structure of the common superficial fascia, which exactly resembles the superficial fascia in every other situation. The common superficial fascia is then to be removed to the same extent, exposing the superficial perineal fascia. This layer is also to be turned aside, when the muscles of the genital region of the perineum will be brought into view.

The Acceleratores urinae (bulbo-cavernosus) arise from a tendinous point in the centre of the perineum and from the fibrous raphé of the two muscles. From these origins the fibres diverge, like the plumes of a pen; the posterior fibres to be inserted into the ramus of the pubes and ischium; the middle to encircle the corpus spongiosum, and meet upon its upper side; and the anterior to spread out upon the corpus cavernosum on each side, and be inserted, partly into its fibrous structure, and partly into the fascia of the penis. The posterior and middle insertions of these muscles are best seen, by carefully raising one muscle from the corpus spongiosum and tracing its fibres.

Relations.—By their superficial surface with the superficial perineal fascia, the dartos, the superficial vessels and nerves of the perineum, and on each side with the erector penis. By their deep surface with the corpus spongiosum and bulb of the urethra.

The Erector penis (ischio-cavernosus) arises from the ramus and tuberosity of the ischium, and curves around the root of the penis, to be inserted into the upper surface of the corpus cavernosum, where it is continuous with a strong fascia which covers the dorsum of the organ, the fascia penis.

Relations.—By its superficial surface with the superficial perineal fascia, the dartos, and the superficial perineal vessels and nerve. By its deep surface with the corpus cavernosum penis.

The Compressor urethrae (Wilson's and Guthrie's muscles), consists of two portions; one of which is transverse in its direction, and passes inwards, to embrace the membranous urethra; the other is perpendicular, and descends from the pubes. The transverse portion, particularly described by Mr. Guthrie, arises by a narrow tendinous point, from the upper part of the ramus of the ischium, on each side, and divides into two fasciculi, which pass inwards and slightly up-
wards, and embrace the membranous portion of the urethra and Cowper's glands. As they pass towards the urethra, they spread out and become fan-shaped, and are inserted into a tendinous raphe upon the upper and lower surfaces of the urethra, extending from the apex of the prostate gland, to which they are attached posteriorly, to the bulbous portion of the urethra, with which they are connected in front. When seen from above, these portions resemble two fans, connected by their expanded border along the middle line of the membranous urethra, from the prostate to the bulbous portion of the urethra. The same appearance is obtained by viewing them from below.

The perpendicular portion† described by Mr. Wilson, arises by two tendinous points from the inner surface of the arch of the pubes, on each side of, and close to, the symphysis. The tendinous origins soon become muscular, and descend perpendicularly, to be inserted into the

* The muscles of the perineum. 1. The acceleratores urinæ muscles; the figure rests upon the corpus spongiosum penis. 2. The corpus cavernosum of one side. 3. The erector penis of one side. 4. The transversus perinei of one side. 5. The triangular space through which the deep perineal fascia is seen. 6. The sphincter ani; its anterior extremity is cut off. 7. The levator ani of the left side; the deep space between the tuberosity of the ischium (8) and the anus, is the ischio-rectal fossa; the same fossa is seen upon the opposite side. 9. The spine of the ischium. 10. The left coccygeus muscle. The boundaries of the perineum are well seen in this engraving.

† Mr. Tyrrell who made many careful dissections of the muscles of the perineum, did not observe this portion of the muscle; he considers Wilson's muscle (with some other anatomists) to be the anterior fibres of the levator ani, not uniting beneath the urethra as described by Mr. Wilson; but inserted into a portion of the pelvic fascia situated between the prostate gland and rectum, the recto-vesical fascia.
upper fasciculus of the transverse portion of the muscle; so that it is not a distinct muscle surrounding the membranous portion of the urethra, and supporting it as in a sling, as described by Mr. Wilson, but merely an upper origin of the transverse muscle.

The compressor urethrae may be considered either as two symmetrical muscles meeting at the raphe, or as a single muscle: I have adopted the latter course in the above description, as appearing to me the more consistent with the general connections of the muscle, and with its actions.

The Transversus perinei arises from the tuberosity of the ischium on each side, and is inserted into the central tendinous point of the perineum.*

"Relations."—By its superficial surface with the superficial perineal fascia, and superficial perineal artery. By its deep surface with the deep perineal fascia, and internal pudic artery and veins. By its posterior border it is in relation with that portion of the superficial perineal fascia which passes back to become continuous with the deep fascia.

To dissect the compressor urethrae, the whole of the preceding muscles should be removed, so as to render the glistening surface of the deep perineal fascia quite apparent. The anterior layer of this fascia should then be carefully dissected away, and the corpus spongiosum penis divided through its middle, separated from the corpus cavernosum, and drawn forwards, to put the membranous portion of the urethra, upon which the muscle is spread out, on the stretch. The muscle is, however, better seen in a dissection made from within the pelvis, after having turned down the bladder from its attachment to the os pubis, and removed a plexus of veins and the posterior layer of the deep perineal fascia.

The Sphincter ani is a thin and elliptical plane of muscle closely adherent to the integument, and surrounding the opening of the anus. It arises posteriorly in the superficial fascia around the coccyx, and by a fibrous raphe from the apex of that bone; and is inserted anteriorly into the tendinous centre of the perineum, and into the raphe of the integument, nearly as far forwards as the commencement of the scrotum.

"Relations."—By its superficial surface with the integument. By its deep surface with the internal sphincter, the levator ani, the cellular tissue and fat in the ischio-rectal fossa, and in front with the superficial perineal fascia.

The Sphincter ani internus is a muscular ring embracing the extremity of the intestine, and formed by an aggregation of the circular muscular fibres of the rectum.

* I have twice dissected a perineum in which the transversus perinei was of large size, and spread out as it approached the middle line so as to become fan-shaped. The posterior fibres were continuous with those of the muscle of the opposite side; but the anterior were prolonged forwards upon the bulb and corpus spongiosum of the urethra as far as the middle of the penis, forming a broad layer which usurped the place and office of the accelerator urinæ.
Part of the levator ani may be seen during the dissection of the anal portion of the perineum by removing the fat which surrounds the termination of the rectum in the ischio-rectal fossa. But, to study the entire muscle, a lateral section of the pelvis must be made by sawing through the pubes a little to one side of the symphysis, separating the bones behind at the sacro-iliac symphysis, and turning down the bladder and rectum. The pelvic fascia is then to be carefully raised, beginning at the base of the bladder and proceeding upwards, until the whole extent of the muscle is exposed.

The Levator ani is a thin plane of muscular fibres, situated on each side of the pelvis. The muscle arises from the inner surface of the os pubis, from the spine of the ischium, and between those points from the angle of division between the obturator and the pelvic fascia. Its fibres descend to be inserted into the extremity of the coccyx into a fibrous raphé in front of that bone, into the lower part of the rectum, base of the bladder, and prostate gland.

In the female this muscle is inserted into the coccyx and fibrous raphé, lower part of the rectum and vagina.

Relations.—By its external or perineal surface, with a thin layer of fascia, by which, and by the obturator fascia, it is separated from the obturator internus muscle; with the fat in the ischio-rectal fossa, the deep perineal fascia, the levator ani, and posteriorly with the gluteus maximus. By its internal or pelvic surface with the pelvic fascia, which separates it from the viscera of the pelvis and peritoneum.

The Coccygeus muscle is a tendino-muscular layer of a triangular form. It arises from the spine of the ischium, and is inserted into the side of the coccyx and lower part of the sacrum.

Relations.—By its internal or pelvic surface, with the rectum; by its external surface with the lesser and greater sacro-ischatic ligaments.

The muscles of the perineum in the female are the same as in the male, and have received analogous names. They are smaller in size, and are modified to suit the different form of the organs; they are—

Constrictor vaginae,
Erector clitoridis,
Transversus perinei,
Compressor urethrae,
Sphincter ani,
Levator ani,
Coccygeus.

The Constrictor vaginae is analogous to the acceleratores urinæ; it is continuous posteriorly with the sphincter ani, interlacing with its fibres, and is inserted anteriorly into the sides of the corpora cavernosa, and fascia of the clitoris.

The Transversus perinei is inserted into the side of the constrictor vaginae, and the levator ani into the side of the vagina.

The other muscles are precisely similar in their attachments to those in the male.
Actions.—The acceleratores urinæ being continuous at the middle line, and attached on each side to the bone, by means of their posterior fibres will support the bulbous portion of the urethra, and acting suddenly will propel the semen, or the last drops of urine from the canal. The posterior and middle fibres, according to Krause,* contribute towards the erection of the corpus spongiosum, by producing compression upon the venous structure of the bulb; and the anterior fibres, according to Tyrrell,† assist in the erection of the entire organ by compressing the vena dorsalis, by means of their insertion into the fascia penis. The erector penis becomes entitled to its name from spreading out upon the dorsum of the organ, into a membranous expansion (fascia penis), which, according to Krause, compresses the dorsal vein during the action of the muscle, and especially after the erection of the organ has commenced. The transverse muscles serve to steady the tendinous centre, that the muscles attached to it may obtain a firm point of support. According to Cruveilhier, they draw the anus backwards during the expulsion of the faeces, and antagonise the levatores ani which carry the anus forwards. The compressor urethrae taking its fixed point from the ramus of the ischium at each side, can, says Mr. Guthrie, “compress the urethra so as to close it; I conceive completely, after the manner of a sphincter.” The transverse portion will also have a tendency to draw the urethra downwards, whilst the perpendicular portion will draw it upwards towards the os pubis. The inferior fasciculus of the transverse muscle, enclosing Cowper’s glands, will assist those bodies in evacuating their secretion. The external sphincter being a cutaneous muscle contracts the integument around the anus, and by its attachment to the tendinous centre, and to the point of the coccyx, assists the levator ani in giving support to the opening during expulsive efforts. The internal sphincter contracts the extremity of the cylinder of the intestine. The use of the levator ani is expressed in its name. It is the antagonist of the diaphragm and the rest of the expulsive muscles, and serves to support the rectum and vagina during their expulsive efforts. The levator ani acts in unison with the diaphragm, and rises and falls like that muscle in forcible respiration. Yielding to the propulsive action of the abdominal muscles, it enables the outlet of the pelvis to bear a greater force than a resisting structure, and on the remission of such action it restores the perineum to its original form. The coccygei muscles restore the coccyx to its natural position, after it has been pressed backwards during defaecation or during parturition.

MUSCLES OF THE UPPER EXTREMITY.

The muscles of the upper extremity may be arranged into groups corresponding with the different regions of the limb, thus:

**Anterior Thoracic Region.**
- Pectoralis major,
- Pectoralis minor,
- Subclavius.

**Lateral Thoracic Region.**
- Serratus magnus.

**Anterior Scapular Region.**
- Subscapularis.

**Posterior Scapular Region.**
- Supra-spinatus,
- Infra-spinatus,
- Teres minor,
- Teres major.

**Acromial Region.**
- Deltoid.

**Anterior Humeral Region.**
- Coraco-brachialis,
- Biceps,
- Brachialis anticus.

**Posterior Humeral Region.**
- Triceps.

**Anterior Brachial Region.**

**Superficial layer.**
- Pronator radii teres,
- Flexor carpi radialis,
- Palmaris longus,
- Flexor sublimis digitorum,
- Flexor carpi ulnaris.

**Deep layer.**
- Flexor profundus digitorum,
- Flexor longus pollicis,
- Pronator quadratus.

**Posterior Brachial Region.**

**Superficial layer.**
- Supinator longus,
- Extensor carpi radialis longior,
- Extensor carpi radialis brevior,
- Extensor communis digitorum,
- Extensor minimi digiti,
- Extensor carpi ulnaris,
- Anconeus.

**Deep layer.**
- Supinator brevis,
- Extensor ossis metacarpi pollicis,
- Extensor primi internodii pollicis,
- Extensor secundi internodii pollicis,
- Extensor indicis.
MUSCLES OF THE UPPER EXTREMITY.

HAND.

Radial Region (Thenar).
- Abductor pollicis
- Flexor ossis metacarpi (opponens)
- Flexor brevis pollicis
- Adductor pollicis

Anterior Thoracic Region.
- Pectoralis major,
- Pectoralis minor,
- Subclavius

Dissection.—Make an incision along the line of the clavicle, from the upper part of the sternum to the acromion process; a second along the lower border of the great pectoral muscle, from the lower end of the sternum to the insertion of its tendon into the humerus; and connect the two by a third, carried longitudinally along the middle of the sternum. The integument and superficial fascia are to be dissected together from off the fibres of the muscle, and always in the direction of their course. For this purpose the dissector, if he have the right arm, will commence with the lower angle of the flap; if the left, with the upper angle. He will thus expose the pectoralis major muscle in its whole extent.

The Pectoralis major muscle arises from the sternal two-thirds of the clavicle, from one half the breadth of the sternum its whole length, from the cartilages of all the true ribs, excepting the first and last, and from the aponeurosis of the external oblique muscle of the abdomen. It is inserted by a broad tendon into the anterior bicipital ridge of the humerus.

That portion of the muscle which arises from the clavicle, is separated from that connected with the sternum by a distinct cellular interspace; hence we speak of the clavicular portion and sternal portion of the pectoralis major. The fibres from this very extensive origin converge towards a narrow insertion, giving the muscle a radiated appearance. But there is a peculiarity about the formation of its tendon which must be carefully noted. The whole of the lower border is folded inwards upon the upper portion, so that the tendon is doubled upon itself. Another peculiarity results from this arrangement: the fibres of the upper portion of the muscle are inserted into the lower part of the bicipital ridge; and those of the lower portion, into the upper part.
Relations.—By its **external surface** with the fibres of origin of the platysma myoides, the mammary gland, the superficial fascia and integument. By its **internal surface**, on the thorax, with the clavicle, the sternum, the costal cartilages, intercostal muscles, subclavius, pectoralis minor, and serratus magnus; in the axilla, with the axillary vessels and glands. By its **external border** with the deltoid, from which it is separated above by a cellular interspace lodging the cephalic vein and the descending branch of the thoraco-acromialis artery. Its **lower border** forms the anterior boundary of the axillary space.

The pectoralis major is now to be removed by dividing its fibres along the lower border of the clavicle, and then carrying the incision perpendicularly downwards, parallel to the sternum, and at about three inches from its border. Divide some loose cellular tissue, and several small branches of the thoracic arteries, and reflect the muscle outwards. We thus bring into view a region of considerable interest, in the middle of which is situated the pectoralis minor.

The **PECTORALIS MINOR** arises by three digitations from the third, fourth, and fifth ribs, and is inserted into the anterior border of the coracoid process of the scapula by a broad tendon.

**Relations.**—By its **anterior surface** with the pectoralis major and superior thoracic vessels and nerves. By its **posterior surface** with the ribs, the intercostal muscles, serratus magnus, axillary space, and axillary vessels and nerves. Its **upper border** forms the lower boundary of a triangular space bounded above by the costo-coracoid membrane, and internally by the ribs. In this space are found the axillary vessels and nerves, and in it the subclavian artery may be tied below the clavicle.

The **SUBCLAVIUS** muscle arises by a round tendon from the cartilage of the first rib, and is inserted into the under surface of the clavicle. This muscle is concealed by the costo-coracoid membrane, an extension of the deep cervical fascia, by which it is invested.

**Relations.**—By its **upper surface** with the clavicle. By the **lower** with the subclavian artery and vein and brachial plexus, which separate it from the first rib. In **front** with the pectoralis major, the costo-coracoid membrane being interposed.

**Actions.**—The pectoralis major draws the arm against the thorax, while its upper fibres assist the upper part of the trapezius in raising the shoulder, as in supporting weights. The lower fibres depress the shoulder with the aid of the latissimus dorsi. Taking its fixed point from the shoulder, the pectoralis major assists the pectoralis minor, subclavius, and serratus magnus, in drawing up and expanding the chest. The pectoralis minor, in addition to this action, draws upon the coracoid process, and assists in rotating the scapula upon the chest. The subclavius draws the clavicle downwards and forwards, and thereby assists in steadying the shoulder. All the muscles of this group are agents in forced respiration, but are incapable of acting until the shoulders are fixed.
LATERAL THORACIC REGION.

Lateral Thoracic Region.

Serratus magnus.

The Serratus magnus (serratus, indented like the edge of a saw,) arises by fleshy serrations from the nine upper ribs excepting the first, and extends backwards upon the side of the chest, to be inserted into the whole length of the base of the scapula upon its anterior aspect. In structure the muscle is composed of three portions, a superior portion formed by two serrations attached to the second rib, and inserted into the inner surface of the superior angle of the scapula, a middle portion composed of the serrations connected with the third and fourth ribs, and inserted into the greater part of the posterior border, and an inferior portion consisting of the last five serrations which indigitate with the obliquus externus and form a thick muscular fasciculus which is inserted into the scapula near its inferior angle.

Relations.—By its superficial surface with the pectoralis major and minor, the subscapularis, and the axillary vessels and nerves. By its deep surface with the ribs and intercostal muscles, to which it is connected by an extremely loose cellular tissue.

Actions.—The serratus magnus is the great external inspiratory muscle, raising the ribs when the shoulders are fixed, and thereby increasing the cavity of the chest. Acting upon the scapula, it draws the shoulder forwards, as we see to be the case in diseased lungs, where the chest has become almost fixed from apprehension of the expanding action of the respiratory muscles.

Anterior Scapular Region.

Subscapularis.

The Subscapularis muscle arises from the whole of the under surface of the scapula excepting the superior and inferior angle, and terminates by a broad and thick tendon, which is inserted into the lesser tuberosity of the humerus. The substance of the muscle is traversed by several intersecting membranous layers from which muscular fibres arise, the intersections being attached to the ridges on the surface of the scapula. Its tendon forms part of the capsule of the joint, glides over a large bursa which separates it from the base of the coracoid process, and is lined by a prolongation of the synovial membrane of the articulation.

Relations.—By its anterior surface with the serratus magnus, coracobrachialis, and axillary vessels and nerves. By its posterior surface with the scapula, the subscapular vessels and nerves, and the shoulder, joint.

Action.—It rotates the head of the humerus inwards, and is a powerful defence to the joint. When the arm is raised, it draws the humerus downwards.
**Posterior Scapular Region.**

**Supra-spinatus,**  
**Infra-spinatus,**  
**Teres minor,**  
**Teres major.**

The **Supra-spinatus** muscle (*supra*, above; *spina*, the spine) arises from the whole of the supra-spinous fossa, and is *inserted* into the uppermost depression on the great tuberosity of the humerus. The tendon of this muscle cannot be well seen until the acromion process is removed.

**Relations.**—By its *upper surface* with the trapezius, the clavicle, acromion, and coraco-acromion ligament. From the trapezius it is separated by a strong fascia. By its *lower surface* with the supra-spinous fossa, the supra-scapular vessels and nerve, and the upper part of the shoulder-joint, forming part of the capsular ligament.

The **Infra-spinatus** (*infra*, beneath; *spina*, the spine) is covered in by a layer of tendinous fascia, which must be removed before the fibres of the muscle can be seen, the deltoid muscle having been previously turned down from its scapular origin. It *arises* from the whole of the infra-spinous fossa, and from the fascia above-mentioned, and is *inserted* into the middle depression upon the greater tuberosity of the humerus.

**Relations.**—By its *posterior surface* with the deltoid, latissimus dorsi and integument. By its *anterior surface* with the infra-spinous fossa, superior and dorsal scapular vessels, and shoulder-joint; its tendon being lined by a prolongation from the synovial membrane. By its *upper border* it is in relation with the spine of the scapula, and by the *lower* with the teres minor, with which it is closely united.

The **Teres minor** muscle (*teres*, round) *arises* from the middle third of the inferior border of the scapula, and is *inserted* into the lower depression on the great tuberosity of the humerus. The tendons of these three muscles, with that of the subscapularis, are in immediate contact with the shoulder-joint, and form part of its ligamentous capsule, thereby preserving the solidity of the articulation. They are therefore the structures most frequently ruptured in dislocation of the head of the humerus.

**Relations.**—By its *posterior surface* with the deltoid, latissimus dorsi and integument. By its *anterior surface* with the inferior border, and part of the dorsum of the scapula, the dorsalis scapulae vessels, scapular head of the triceps, and shoulder-joint. By its *upper border* with the infra-spinatus; and by the *lower* with the latissimus dorsi, teres major, and long head of the triceps.

The **Teres major** muscle *arises* from the lower third of the inferior border of the scapula, encroaching a little upon its dorsal aspect, and is *inserted* into the posterior bicipital ridge. Its tendon lies immediately behind that of the latissimus dorsi, from which it is separated by a synovial membrane.

**Relations.**—By its *posterior surface* with the latissimus dorsi, sc-
pular head of the triceps and integument. By its anterior surface
with the subscapularis, latissimus dorsi, coraco-brachialis, short head
of the biceps, axillary vessels, and branches of the brachial plexus. By
its upper border it is in relation with the teres minor, from which it
is separated by the scapular head of the triceps, and by the lower it
forms with the latissimus dorsi the lower and posterior border of the
axilla.

A large triangular space exists between the two teres muscles,
which is divided into two minor spaces by the long head of the
triceps.

Actions.—The supra-spinatus raises the arm from the side; but
only feebly, from the disadvantageous direction of the force. The
infra-spinatus and teres minor are rotators of the head of the humerus
outwards. The most important use of these three muscles is the pro-
tection of the joint, and defence against displacement of the head of
the humerus, in which action they co-operate with the subscapularis.
The teres major combines, with the latissimus dorsi, in rotating the
arm inwards, and at the same time carrying it towards the side, and
somewhat backwards.

Acromial Region.

Deltoid.

The convexity of the shoulder is formed by a large triangular
muscle, the deltoïd (Δ, delta; δέτος, resemblance), which arises from the
outer third of the clavicle, from the acromion process, and from the whole
length of the spine of the scapula. The fibres from this broad origin
converge to the middle of the outer side of the humerus, where they
are inserted into a rough triangular elevation. This muscle is remark-
able for its coarse texture, and for its numerous tendinous intersections
from which muscular fibres arise. The deltoïd muscle may now be
cut away from its origin, and turned down, for the purpose of bring-
ing into view the muscles and tendons placed immediately around the
shoulder-joint. In so doing, a large bursa will be seen between the
under surface of the muscle and the head of the humerus.

Relations.—By its superficial surface with a thin aponeurotic fascia,
a few fibres of the platysma myoides, the superficial fascia and in-
tegument. By its deep surface with the shoulder-joint, from which
it is separated by a thin tendinous fascia, and by a synovial bursa;
with the coraco-acromial ligament, coracoid process, pectoralis minor,
coraco-brachialis, both heads of the biceps, tendon of the pectoralis
major, tendon of the supra-spinatus, infra-spinatus, teres minor, teres
major, scapular and external head of the triceps, the circumflex
vessels anterior and posterior, and humerus. By its anterior border
with the external border of the pectoralis major, from which it is
separated by a cellular interspace, lodging the cephalic vein and
descending branch of the thoracico-acromialis artery. Its posterior
border is thin and tendinous above, where it is connected with the aponeurotic covering of the infra-spinatus muscle, and thick below.

Actions.—The deltoid is the elevator muscle of the arm in a direct line, and by means of its extensive origin can carry the arm forwards or backwards so as to range with the hand a considerable segment of a large circle. The arm, raised by the deltoid, is a good illustration of a lever of the third power, so common in the animal machine, by which velocity is gained at the expense of power. In this lever, the weight (hand) is at one extremity, the fulcrum (the glenoid cavity) at the opposite end, and the power (the insertion of the muscle) between the two, but nearer to the fulcrum than to the weight.

**Anterior Humeral Region.**

Coraco-brachialis,
Biceps,
Brachialis anticus.

Dissection.—These muscles are exposed, on the removal of the integument and fascia from the anterior half of the upper arm, and the clearing away of the cellular tissue.

The Coraco-brachialis, a name composed of its points of origin and insertion, arises from the coracoid process in common with the short head of the biceps; and is inserted into a rough line on the inner side of the middle of the humerus.

Relations.—By its anterior surface with the deltoid, and pectoralis major. By its posterior surface with the shoulder-joint, the humerus, subscapularis, teres major, latissimus dorsi, short head of the triceps, and anterior circumflex vessels.

Fig. 96.*

* The muscles of the anterior aspect of the upper arm. 1. The coracoid process of the scapula. 2. The coraco-clavicular ligament (trapezoid), passing upwards to the scapular end of the clavicle. 3. The coraco-acromial ligament, passing outwards to the acromion. 4. The subscapularis muscle. 5. The teres major; the triangular space above this muscle is that through which the dorsalis scapulae vessels pass. 6. The coraco-brachialis. 7. The biceps. 8. The upper end of the radius. 9. The brachialis anticus; a portion of the muscle is seen on the outer side of the tendon of the biceps. 10. The internal head of the triceps.
By its internal border with the axillary and brachial vessels and nerves, particularly with the median and external cutaneous nerve, by the latter of which it is pierced. By the external border with the short head of the biceps and brachialis anticus.

The Biceps (bis—κιφαλεῖ two heads) arises by two tendons, one the short head, from the coracoid process in common with the coracobrachialis; the other the long head, from the upper part of the glenoid cavity. The muscle is inserted by a rounded tendon, into the tubercle of the radius. The long head, a long slender tendon, passes through the capsular ligament of the shoulder-joint enclosed in a sheath of the synovial membrane; after leaving the cavity of the joint, it is lodged in the deep groove that separates the two tuberosities of the humerus, the bicipital groove. A small synovial bursa is interposed between the tendon of insertion, and the tubercle of the radius. At the bend of the elbow, the tendon of the biceps gives off from its inner side a broad tendinous band, which protects the brachial artery, and is continuous with the fascia of the fore-arm.

Relations.—By its anterior surface with the deltoid, pectoralis major, superficial and deep fascia and integument. By its posterior surface the short head rests upon the subscapularis, from which it is separated by a bursa. In the rest of its extent the muscle is in relation with the humerus, the teres major, latissimus dorsi, and brachialis anticus; from the latter it is separated by the external cutaneous nerve. By its inner border with the coraco-brachialis, brachial artery and veins, and median nerve; the brachial vessels crossing its tendon at the bend of the elbow. By its outer border with the deltoid and supinator longus.

The Brachialis anticus is a broad muscle covering the whole of the anterior surface of the lower part of the humerus; it arises by two fleshy serrations from the depressions on either side of the insertion of the deltoid, from the anterior surface of the humerus, and from the intermuscular septa attached to the condyloid ridges. Its fibres converge to be inserted into the coromoid process of the ulna.

Relations.—By its anterior surface with the biceps, external cutaneous nerve, brachial artery and veins, and median nerve. By its posterior surface with the humerus, anterior ligament of the elbow-joint, and intermuscular aponeurosis. The latter separates it from the triceps. By its external border with the supinator longus, extensor carpi radialis longior, musculo-spiral nerve, and recurrent radial artery. By its internal border with the intermuscular aponeurosis, which separates it from the triceps and ulnar nerve, and with the pronator radii teres.

Actions.—The coraco-brachialis draws the humerus inwards, and assists in flexing it upon the scapula. The biceps and brachialis anticus are flexors of the fore-arm, and the former a supinator. The brachialis anticus is a powerful protection to the elbow-joint.
Posterior Humeral Region.

Triceps extensor cubiti.

Dissection.—Remove the integument and fascia from the posterior aspect of the upper arm. The Triceps (τρεῖς κυσαλαί, three heads,) arises by three heads. Considered in relation to their length, these heads have been named long, short, and middle; and in reference to their position, internal, external, and middle; the term middle, in the former case, referring to the external head, and in the latter case to the long head. This has given rise to much confusion and misunderstanding. I shall, therefore, confine myself to the designations derived from their relations. The external head arises from the humerus, commencing immediately below the insertion of the teres minor, and from the intermuscular septum attached to the external condyloid ridge. The internal head (short) arises from the humerus, commencing immediately below the insertion of the teres major, and from the intermuscular septum attached to the internal condyloid ridge. The scapular head (long) lies between the two others, and arises from the upper third of the inferior border of the scapula. The three heads unite to form a broad muscle, which is inserted by an aponeurotic tendon into the olecranon process of the ulna; a small bursa is situated between its tendon and the upper part of the olecranon.

The scapular head of the triceps passes between the teres minor and major, and divides the triangular space between those two muscles into two smaller spaces, one of which is triangular, the other quadrangular. The triangular space is bounded by the teres minor, teres major, and scapular head of the triceps; it

* A posterior view of the upper arm, shewing the triceps muscle. 1. Its external head. 2. Its long, or scapular head. 3. Its internal, or short head. 4. The olecranon process of the ulna. 5. The radius. 6. The capsular ligament of the shoulder-joint.
gives passage to the dorsalis scapulae artery and veins. The quadrangular space is bounded on three sides by the three preceding muscles, and on the fourth by the humerus. Through this space pass the posterior circumflex artery and veins, and circumflex nerve.

A few of the deep fibres of the triceps, attached above to the humerus and below to the capsule of the elbow-joint, have been named sub-anconeus; they are analogous to the sub-crureus.

Relations.—By its posterior surface with the deep and superficial fascia and integument. By its anterior surface with the superior profunda artery, musculo-spiral nerve, humerus, intermuscular aponeuroses which separate it from the brachialis anticus, and with the elbow-joint. The scapular head is in relation posteriorly with the deltoid and teres minor; anteriorly with the subscapularis, teres major, and latissimus dorsi; and externally with the posterior circumflex vessels and nerve.

Actions.—The triceps is an extensor of the fore-arm.

**Anterior Brachial Region.**

**Superficial layer.**

Pronator radii teres,
Flexor carpi radialis,
Palmaris longus,
Flexor sublimis digitorum,
Flexor carpi ulnaris.

* Superficial layer of muscles of the fore-arm. 1. The lower part of the biceps, with its tendon. 2. A part of the brachialis anticus, seen beneath the biceps. 3. A part of the triceps. 4. The pronator radii teres. 5. The flexor carpi radialis. 6. The palmaris longus. 7. One of the fasciculi of the flexor sublimis digitorum; the rest of the muscle is seen beneath the tendons of the palmaris longus and flexor carpi radialis. 8. The flexor carpi ulnaris. 9. The palmar fascia. 10. The palmaris brevis muscle. 11. The abductor pollicis muscle. 12. One portion of the flexor brevis pollicis; the leading line crosses a part of the adductor pollicis. 13. The supinator longus muscle. 14. The extensor ossis metacarpi, and extensor primi internodii pollicis, curving around the lower border of the fore-arm.
Dissection.—These muscles are brought into view by making an incision through the integument along the middle line of the fore-arm, crossing each extremity by a transverse incision, and turning aside the flaps. The superficial and deep fascia are then to be removed.

The Pronator radii teres arises by two heads; one from the inner condyle of the humerus, fascia of the fore-arm, and intermuscular aponeurosis; the other, from the coronoid process of the ulna; the median nerve passing between them. Its tendon is flat and inserted into the middle third of the oblique ridge of the radius. The two heads of this muscle are best examined by cutting through that which arises from the inner condyle, and turning it aside. The second head will then be seen with the median nerve lying across it.

Relations.—By its anterior surface with the fascia of the fore-arm, the supinator longus, extensor carpi radialis longior and brevior, radial artery and veins, and radial nerve. By its posterior surface with the brachialis anticus, flexor sublimis digitorum, the ulnar artery and veins, and the median nerve after it has passed between the two heads of the muscle. By its upper border it forms the inner boundary of the triangular space, in which the termination of the brachial artery is situated. By its lower border it is in relation with the flexor carpi radialis.

The Flexor carpi radialis arises from the inner condyle and from the intermuscular fascia. Its tendon passes through a groove formed by the scaphoid bone and trapezium, to be inserted into the base of the metacarpal bone of the index finger.

Relations.—By its anterior surface with the fascia of the fore-arm, and at the wrist with the tendinous canal through which its tendon passes. By its posterior surface with the flexor sublimis digitorum, flexor longus pollicis, wrist-joint, and groove in the scaphoid and trapezium bones. By its outer border with the pronator radii teres, and radial artery and veins. By its inner border with the palmaris longus. The tendon is surrounded by a synovial membrane where it plays through the tendinous canal of the wrist.

The Palmaris longus is a small muscle which arises from the inner condyle, and from the intermuscular fascia. It is inserted into the annular ligament and palmar fascia. Occasionally this muscle is wanting.

Relations.—By its anterior surface with the fascia of the fore-arm, By the posterior surface with the flexor sublimis digitorum; to the external side by the flexor carpi radialis; and to the internal side by the flexor carpi ulnaris.

Cut the flexor carpi radialis and palmaris longus from their origins, in order to obtain a good view of the whole extent of origin of the flexor sublimis digitorum.

The Flexor sublimis digitorum (perforatus) arises from the inner condyle, internal lateral ligament, coronoid process of the ulna, and oblique line of the radius. The median nerve and ulnar artery pass between its origins. It divides into four tendons, which pass be-
neath the annular ligament into the palm of the hand, and are inserted into the base of the second phalanges of the fingers, splitting at their terminations to give passage to the tendons of the deep flexors; thence its designation, perforatus. In the theee of the fingers several small tendinous fasciculi are generally found which pass between the phalanges and the edges of the tendons; these have been termed the vincula accessoria.

Relations.—In the fore-arm. By its anterior surface with the pronator radii teres, flexor carpi radialis, palmaris longus, flexor carpi ulnaris, and the deep fascia. By its posterior surface with the flexor profundus digitorum, flexor longus pollicis, ulnar artery, veins, and nerve, and median nerve. This muscle frequently sends a fasciculus to the flexor longus pollicis or flexor profundus. In the hand: its tendons, after passing beneath the annular ligament, are in relation superficially with the superficial palmar arch, and palmar fascia; and deeply with the tendons of the deep flexor and lumbricales.

The Flexor carpi ulnaris arises by two heads, one from the inner condyle, the other from the olecranon and upper two-thirds of the inner border of the ulna. Its tendon is inserted into the pisiform bone, and base of the metacarpal bone of the little finger.

Relations.—By its anterior surface with the fascia of the fore-arm, with which it is closely united superiorly. By its posterior surface with the flexor sublimis digitorum, flexor profundus, pronator quadratus, and ulnar artery, veins, and nerve. By its radial border with the palmaris longus, and in the lower third of the fore-arm with the ulnar vessels and nerve. The ulnar nerve, and the posterior ulnar recurrent artery, pass between its two heads of origin.

Deep layer.

Flexor profundus digitorum,
Flexor longus pollicis,
Pronator quadratus.

Dissection.—This group is brought into view by removing the flexor sublimis, and drawing aside the pronator radii teres.

The Flexor profundus digitorum (perforans) arises from the upper two-thirds of the ulna and part of the interosseous membrane, and terminates in four tendons, which pass beneath the annular ligament, and between the two slips of the tendons of the flexor sublimis (hence its designation, perforans), to be inserted into the base of the last phalanges. The tendon of the index finger is always distinct from the rest, the other three tendons being more or less intimately connected by cellular tissue and tendinous slips.

Four little muscular fasciculi, called lumbricales, are connected with the tendons of this muscle in the palm. They will be described with the muscles of the hand.

Relations.—In the fore-arm. By its anterior surface with the flexor
sublimis digitorum, flexor carpi ulnaris, median nerve, and ulnar artery, veins, and nerve. By its posterior surface with the ulna, the interosseous membrane, the pronator quadratus, and the wrist-joint. By its radial border with the flexor longus pollicis, the anterior interosseous artery and nerve being interposed. By its ulnar border with the flexor carpi ulnaris. In the hand: its tendons are in relation superficially with the tendons of the superficial flexor; and deeply with the interossei muscles, adductor pollicis, and deep palmar arch. In the fingers: the tendons of the deep flexor are interposed between the tendons of the superficial flexor and the phalanges, and give attachment to vincula accessoria.

The Flexor longus pollicis arises from the upper two-thirds of the radius, and part of the interosseous membrane. Its tendon passes beneath the annular ligament, to be inserted into the base of the last phalanx of the thumb.

Relations.—By its anterior surface with the flexor sublimis digitorum, flexor carpi radialis, supinator longus, and radial artery and veins. By its posterior surface with the radius, interosseous membrane, pronator quadratus, and wrist-joint. By its ulnar border it is separated from the flexor profundus digitorum by the anterior interosseous artery and nerve. In the hand: after passing beneath the annular ligament, it is lodged in the interspace between the two portions of the flexor brevis pollicis, and afterwards in the tendinous theca of the phalanges.

If the tendons of the last two muscles be drawn aside or divided,

* The deep layer of muscles of the fore-arm. 1. The internal lateral ligament of the elbow-joint. 2. The anterior ligament. 3. The orbicular ligament of the head of the radius. 4. The flexor profundus digitorum muscle. 5. The flexor longus pollicis. 6. The pronator quadratus. 7. The adductor pollicis muscle. 8. The dorsal interosseous muscle of the middle finger, and palmar interosseous of the ring-finger. 9. The dorsal interosseous muscle of the ring-finger, and palmar interosseous of the little-finger.
the third muscle of this group will be brought into view, lying across the lower part of the two bones.

The Pronator Quadratus arises from the ulna, and is inserted into the lower fourth of the oblique line, on the outer side of the radius. This muscle occupies about the lower fourth of the two bones, is broad at its origin, and narrower at its insertion.

Relations.—By its anterior surface with the tendons of the supinator longus, flexor carpi radialis, flexor longus pollicis, flexor profundus digitorum, and flexor carpi ulnaris, radial artery and veins, and ulnar artery, veins, and nerve. By its posterior surface with the radius, ulna, and interosseous membrane.

Actions.—The pronator radii teres and pronator quadratus muscles rotate the radius upon the ulna, and render the hand prone. The remaining muscles are flexors: two flexors of the wrist, flexor carpi radialis and ulnaris; two of the fingers, flexor sublimis and profundus, the former flexing the second phalanges, the latter the last; one flexor of the last phalanx of the thumb, flexor longus pollicis. The palmaris longus is primarily a tensor of the palmar fascia, and secondarily a flexor of the wrist and fore-arm.

Posterior Brachial Region.

Superficial layer.

Supinator longus,
Extensor carpi radialis longior,
Extensor carpi radialis brevier,
Extensor communis digitorum,
Extensor minimi digitii,
Extensor carpi ulnaris,
Anconeus.

Dissection.—The integument is to be divided and turned aside, and the fasciae removed in the same manner as for the anterior brachial region.

The Supinator Longus muscle is placed along the radial border of the fore-arm. It arises from the external condyloid ridge of the humerus, nearly as high as the insertion of the deltoid, and is inserted into the base of the styloid process of the radius.

Relations.—By its superficial surface with the extensor ossis metacarpi pollicis, extensor primi internodi pollicis, and fascia of the fore-arm. By its deep surface with the brachialis anticus, extensor carpi radialis longior, tendon of the biceps, supinator brevis, pronator radii teres, flexor carpi radialis, flexor sublimis digitorum, flexor longus pollicis, pronator quadratus, radius, musculo-spiral nerve, radial and posterior interosseous nerve, and radial artery and veins.

This muscle must be divided through the middle, and the two ends turned to either side to expose the next muscle.
The **Extensor carpi radialis longior** arises from the external condyloid ridge below the preceding, and from the intermuscular fascia. Its tendon passes through a groove in the radius, immediately behind the styloid process, to be inserted into the base of the metacarpal bone of the index finger.

**Relations.**—By its superficial surface with the supinator longus, extensor ossis metacarpi pollicis, extensor primi internodii pollicis, extensor secundi internodii pollicis, radial nerve, fascia of the forearm, and posterior annular ligament. By its deep surface with the brachialis anticus, extensor carpi radialis brevior, radius and wrist joint.

The **Extensor carpi radialis brevior** is seen by drawing aside the former muscle. It arises from the external condyle of the humerus and intermuscular fascia, and is inserted into the base of the metacarpal bone of the middle finger. Its tendon is lodged in the same groove on the radius with the extensor carpi radialis longior.

**Relations.**—By its superficial surface with the extensor carpi radialis longior, extensor ossis metacarpi pollicis, extensor primi internodii pollicis, extensor secundi internodii pollicis, fascia of the forearm, and posterior annular ligament. By its deep surface with the

  14. The extensor secundi internodii; its tendon is seen crossing the two tendons of the extensor carpi radialis longior and brevior.  
  15. The posterior annular ligament. The tendons of the common extensor are seen upon the back of the hand, and their mode of distribution on the dorsum of the fingers.
supinator brevis, tendon of the pronator radii teres, radius and wrist-joint. By its *ulnar border* with the extensor communis digitorum.

The *Extensor communis digitorum* *arises* from the external condyle, and intermuscular fascia; and divides into four tendons, which are *inserted* into the second and third phalanges of the fingers. At the metacarpo-phalangeal articulation each tendon becomes narrow and thick, and sends a thin fasciculus upon each side of the joint. It then spreads out and receiving the tendon of the lumbricalis, and some tendinous fasciculi from the interossei, forms a broad aponeurosis, which covers the whole of the posterior aspect of the finger. At the first phalangeal joint the aponeurosis divides into three slips. The middle slip is inserted into the base of the second phalanx, and the two lateral portions are continued onwards on each side of the joint, to be inserted into the last. Little oblique tendinous slips connect the tendons of the middle, ring, and little finger as they cross the back of the hand.

**Relations.**—By its *superficial surface* with the fascia of the fore-arm and back of the hand, and with the posterior annular ligament. By its *deep surface* with the supinator brevis, extensor ossis metacarpi pollicis, extensor primi internodii, extensor secundi internodii, extensor indicis, posterior interosseous artery and nerve, wrist-joint, metacarpal bones and interossei muscles, and phalanges. By its *radial border* with the extensor carpi radialis longior and brevior. By the *ulnar border* with the extensor minimi digiti, and extensor carpi ulnaris.

The *Extensor minimi digiti* (auricularis) is an off-set from the extensor communis, with which it is connected by means of a tendinous slip. Passing down to the inferior extremity of the ulna it traverses a distinct fibrous sheath, and at the metacarpo-phalangeal articulation unites with the tendon derived from the common extensor. The common tendon then spreads out into a broad expansion which divides into three slips to be *inserted* as in the other fingers into the last two phalanges. It is to this muscle that the little finger owes its power of separate extension; and from being called into action when the point of the finger is introduced into the meatus of the ear, for the purpose of removing unpleasant sensations or producing titillation, the muscle was called by the old writers "auricularis."

The *Extensor carpi ulnaris* *arises* from the external condyle and from the upper two-thirds of the border of the ulna. Its tendon passes through the posterior groove in the lower extremity of the ulna, to be *inserted* into the base of the metacarpal bone of the little finger.

**Relations.**—By its *superficial surface* with the fascia of the fore-arm, and posterior annular ligament. By its *deep surface* with the supinator brevis, extensor ossis metacarpi pollicis, extensor secundi internodii, extensor indicis, ulna, and wrist-joint. By its *radial border* it is in relation with the extensor communis digitorum, and extensor minimi digiti, and by the *ulnar border* with the anconeus.

The *Anconeus* is a small triangular muscle having the appearance of being a continuation of the triceps; it *arises* from the outer condyle,
and is inserted into the olecranon and triangular surface on the upper extremity of the ulna.

Relations.—By its superficial surface with a strong tendinous aponeurosis derived from the triceps. By its deep surface with the elbow joint, orbicular ligament, and slightly with the supinator brevis.

Deep Layer.

Supinator brevis,
Extensor ossis metacarpi pollicis.
Extensor primi internodii pollicis,
Extensor secundi internodii pollicis,
Extensor indicis.

Dissection.—The muscles of the superficial layer should be removed in order to bring the deep group completely into view.

The supinator brevis cannot be seen in its entire extent, until the radial extensors of the carpus are divided from their origin. It arises from the external condyle, from the external lateral and orbicular ligament, and from the ulna, and winds around the upper part of the radius, to be inserted into the upper third of its oblique line. The posterior interosseous artery and nerve are seen perforating the lower border of this muscle.

Relations.—By its superficial surface with the pronator radii teres, supinator longus, extensor carpi radialis longior and brevior, extensor communis digitorum, extensor carpi ulnaris, anconeus, the radial artery and veins, the musculo-spiral nerve, radial and posterior interosseus nerve. By its deep surface with the elbow joint and its ligaments, the interosseous membrane, and the radius.

The extensor ossis metacarpi pollicis is placed immediately below the supinator brevis. It arises from the ulna, interosseous membrane, and radius, and is inserted, as its name implies, into the base of the metacarpal bone of the thumb. Its tendon passes through the groove immediately in front of the styloid process of the radius.

Relations.—By its superficial surface with the extensor carpi ulnaris, extensor minimi digiti, extensor communis digitorum, fascia of the forearm, and annular ligament. By its deep surface with the ulna, interosseous membrane, radius, tendons of the extensor carpi radialis longior and brevior, and supinator longus, and at the wrist with the radial artery. By its upper border with the edge of the supinator brevis. By its lower border with the extensor secundi and primi internodii. The muscle is crossed by branches of the posterior interosseous artery and nerve.

The extensor primi internodii pollicis, the smallest of the muscles in this layer, arises from the interosseous membrane and radius, and passes through the same groove with the extensor ossis metacarpi, to be inserted into the base of the first phalanx of the thumb.

Relations.—The same as those of the preceding muscle with the ex-
The muscle accompanies the extensor ossis metacarpi.

The Extensor secundi internodii pollicis arises from the ulna, and interosseous membrane. Its tendon passes through a distinct canal in the annular ligament, and is inserted into the base of the last phalanx of the thumb.

Relations.—By its external surface with the same relations as the extensor ossis metacarpi. By its deep surface with the ulna, interosseous membrane, radius, wrist-joint, radial artery, and metacarpal bone of the thumb. The muscle is placed between the extensor primi internodii and extensor indicis.

The Extensor indicis arises from the ulna, as high up as the extensor ossis metacarpi pollicis, and from the interosseous membrane. Its tendon passes through a distinct groove in the radius, and is inserted into the aponeurosis formed by the common extensor tendon of the index finger.

Relations.—The same as those of the preceding muscle, with the exception of the hand, where the tendon rests upon the metacarpal bone of the fore-finger and second interosseous muscle, and has no relation with the radial artery.

The tendons of the extensors, as of the flexor muscles of the fore-arm, are provided with synovial bursa as they pass beneath the annular ligaments: those of the back of the wrist have distinct sheaths, formed by the posterior annular ligament.

Actions.—The anconeus is associated in its action with the triceps*

---

* The deep layer of muscles on the posterior aspect of the fore-arm. 1. The lower part of the humerus. 2. The olearanon. 3. The ulna. 4. The anconeus muscle. 5. The supinator brevis muscle. 6. The extensor ossis metacarpi pollicis. 7. The extensor primi internodii pollicis. 8. The extensor secundi internodii pollicis. 9. The extensor indicis. 10. The first dorsal interosseous muscle. The other three dorsal interossei are seen between the metacarpal bones of their respective fingers.
extensor cubiti: it assists in extending the fore-arm upon the arm. The supinator longus and brevis effect the supination of the fore-arm, and antagonize the two pronators. The extensor carpi radialis longior and brevior, and ulnaris, extend the wrist in opposition to the two flexors of the carpus. The extensor communis digitorum restores the fingers to the straight position, after being flexed by the two flexors, sublimis and profundus. The extensor ossis metacarpi, primi internodii, and secundi internodii pollicis, are the especial extensors of the thumb, and serve to balance the actions of the flexor ossis metacarpi, flexor brevis, and flexor longus pollicis. The extensor indicis gives the character of extension to the index finger, and is hence named "indicator," and the extensor minimi digiti supplies that finger with the power of exercising a distinct extension.

MUSCLES OF THE HAND.

Radial or Thenar Region.

Abductor pollicis,
Flexor ossis metacarpi (opponens),
Flexor brevis pollicis,
Adductor pollicis.

Dissection.—The hand is best dissected by making an incision along the middle of the palm, from the wrist to the base of the fingers, and crossing it at each extremity by a transverse incision, then turning aside the flaps of integument. For exposing the muscles of the radial region, the removal of the integument and fascia on the radial side will be sufficient.

The Abductor pollicis is a small, thin muscle, which arises from the scaphoid bone and annular ligament. It is inserted into the base of the first phalanx of the thumb.

Relations.—By its superficial surface with the external portion of the palmar fascia. By its deep surface with the flexor ossis metacarpi. On its inner side it is separated by a narrow cellular interspace from the flexor brevis pollicis.

This muscle must be divided from its origin and turned upwards, in order to see the next.

The Flexor ossis metacarpi (opponens pollicis) arises from the trapezium and annular ligament, and is inserted into the whole length of the metacarpal bone.

Relations.—By its superficial surface with the abductor pollicis. By its deep surface with the trapezio-metacarpal articulation and with the metacarpal bone. Internally with the flexor brevis pollicis.

The flexor ossis metacarpi may now be divided from its origin and turned aside, in order to shew the next muscle.

The Flexor brevis pollicis consists of two portions, between which lies the tendon of the flexor longus pollicis. The external portion
arises from the trapezium and annular ligament; the internal portion from the trapezoides and os magnum. They are both inserted into the base of the first phalanx of the thumb, having a sesamoid bone in each of their tendons to protect the joint.

*Fig. 102.*

**Relations.**—By its superficial surface with the external portion of the palmar fascia. By its deep surface with the adductor pollicis, tendon of the flexor carpi radialis, and trapezio-metacarpal articulation.

* The muscles of the hand. 1. The annular ligament. 2, 2. The origin and insertion of the abductor pollicis muscle; the middle portion has been removed. 3. The flexor ossis metacarpi, or opponens pollicis. 4. One portion of the flexor brevis pollicis. 5. The deep portion of the flexor brevis pollicis. 6. The adductor pollicis. 7, 7. The lumbricales muscles, arising from the deep flexor tendons, upon which the numbers are placed. The tendons of the flexor sublimis have been removed from the palm of the hand. 8. One of the tendons of the deep flexor, passing between the two terminal slips of the tendon of the flexor sublimis to reach the last phalanx. 9. The tendon of the flexor longus pollicis, passing between the two portions of the flexor brevis to the last phalanx. 10. The abductor minimi digitii. 11. The flexor brevis minimi digitii. The edge of the flexor ossis metacarpi, or adductor minimi digitii, is seen projecting beyond the inner border of the flexor brevis. 12. The prominence of the pisiform bone. 13. The first dorsal inter-osseous muscle.
By its external surface with the flexor ossis metacarpi and metacarpal bone. By its inner surface with the tendons of the long flexor muscles and first lumbricalis.

The Adductor Pollicis is a triangular muscle; it arises from the whole length of the metacarpal bone of the middle finger; and the fibres converge to its insertion into the base of the first phalanx.

Relations.—By its anterior surface with the flexor brevis pollicis, tendons of the deep flexor of the fingers, lumbricales, and deep palmar arch. By its posterior surface with the metacarpal bones of the index and middle fingers, the interossei of the second interosseous space, and the abductor indicis. Its inferior border is subcutaneous.

Ulnar, or Hypothenar Region.

Palmaris brevis,
Abductor minimi digiti,
Flexor brevis minimi digiti,
Flexor ossis metacarpi (adductor).

Dissection.—Turn aside the ulnar flap of integument in the palm of the hand; in doing this, a small subcutaneous muscle, the palmaris brevis will be exposed. After examining this muscle, remove it with the deep fascia, in order to bring into view the muscles of the little finger.

The Palmaris brevis is a thin plane of muscular fibres which arises from the annular ligament and palmar fascia, and passes transversely inwards, to be inserted into the integument on the inner border of the hand.

Relations.—By its superficial surface with the fat and integument of the ball of the little finger. By its deep surface with the internal portion of the palmar fascia, which separates it from the ulnar artery, veins, and nerve, and from the muscles of the inner border of the hand.

The Adductor Minimi Digitii is a small tapering muscle which arises from the pisiform bone, and is inserted into the base of the first phalanx of the little finger.

Relations.—By its superficial surface with the internal portion of the deep fascia and the palmaris brevis; by its deep surface with the flexor ossis metacarpi and metacarpal bone. By its inner border with the flexor brevis minimi digiti.

The Flexor brevis minimi digitii is a small muscle arising from the unciform bone and annular ligament, and inserted into the base of the first phalanx. It is sometimes wanting.

Relations.—By its superficial surface with the internal portion of the palmar fascia, and the palmaris brevis. By its deep surface with the flexor ossis metacarpi, and metacarpal bone. Externally with the abductor minimi digiti, from which it is separated near its origin by the deep palmar branch of the ulnar nerve and communicating artery. Internally with the tendons of the flexor sublimis and profundus.
The **Flexor ossis metacarpi** (adductor, opponens) *arises* from the unciform bone and annular ligament, and is *inserted* into the whole length of the metacarpal bone of the little finger.

**Relations.**—By its superficial surface with the flexor brevis and adductor minimi digiti. By its deep surface with the interossei muscles of the last metacarpal space, the metacarpal bone, and the flexor tendons of the little finger.

**Palmar Region.**

Lumbricales,
Interossei palmares,
Interossei dorsales.

The **Lumbricales**, four in number, are accessories to the deep flexor muscle. They *arise* from the tendons of the deep flexor; the first and second from the palmar side, the third from the ulnar, and the fourth from the radial side; and are *inserted* into the aponeurotic expansion of the extensor tendons on the radial side of the fingers. The third, or that of the tendon of the ring finger, sometimes bifurcates, otherwise it is inserted wholly into the extensor tendon of the middle finger.

**Relations.**—In the palm of the hand with the flexor tendons; at their insertion, with the tendons of the interossei and the metacarpophalangeal articulations.

The **Palmar interossei**, three in number, are placed upon the metacarpal bones, rather than between them. They *arise* from the base of the metacarpal bone of one finger, and are *inserted* into the base of the first phalanx and aponeurotic expansion of the extensor tendon of the same finger. The first belongs to the index finger; the second, to the ring finger; and the third, to the little finger; the middle finger being excluded.

**Relations.**—By their palmar surface with the flexor tendons and with the deep muscles in the palm of the hand. By their dorsal surface with the dorsal interossei. On one side with the metacarpal bone, on the other with the corresponding dorsal interosseous.

**Dorsal interossei.**—On turning to the dorsum of the hand, the four dorsal interossei are seen in the four spaces between the metacarpal bones. They are bipenniform muscles, and *arise* by two heads, from the adjoining sides of the base of the metacarpal bones. They are *inserted* into the base of the first phalanges, and aponeurosis of the extensor tendons.

The first is inserted into the index finger, and from its use is called abductor indicis; the second and third are inserted into the middle finger, compensating its exclusion from the palmar group; the fourth is attached to the ring finger; so that each finger is provided with two interossei, with the exception of the little finger, as may be shewn by means of a table, thus:—
Index finger \{ one dorsal (abductor indicis), \\
    one palmar.
Middle finger, two dorsal.
Ring finger \{ one dorsal, \\
    one palmar.
Little finger, remaining palmar.

Relations.—By their dorsal surface with a thin aponeurosis which separates them from the tendons on the dorsum of the hand. By their palmar surface with the muscles and tendons in the palm of the hand. By one side with the metacarpal bone; by the other with the corresponding palmar interosseous. The abductor indicis is in relation by its palmar surface, with the adductor pollicis, the arteria magna pollicis being interposed. The radial artery passes into the palm of the hand between the two heads of the first dorsal interosseous muscle and the perforating branches of the deep palmar arch, between the heads of the other dorsal interossei.

Actions.—The actions of the muscles of the hand are expressed in their names. Those of the radial region belong to the thumb, and provide for three of its movements, abduction, adduction, and flexion. The ulnar group, in like manner, are subservient to the same motions of the little finger, and the interosseous are abductors and adductors of the several fingers. The lumbricales are accessory in their actions to the deep flexors: they were called by the earlier anatomists, fidicinii, i.e. fiddlers’ muscles, from an idea that they might effect the fractional movements by which the performer is enabled to produce the various notes on that instrument.

In relation to the axis of the hand, the four dorsal interossei are abductors, and the three palmar, adductors. It will therefore be seen that each finger is provided with its proper adductor and abductor, two flexors, and (with the exception of the middle and ring fingers) two extensors. The thumb has moreover a flexor and extensor of the metacarpal bone; and the little finger a flexor of the metacarpal bone without an extensor.
MUSCLES OF THE LOWER EXTREMITY.

The muscles of the lower extremity may be arranged into groups corresponding with the regions of the hip, thigh, leg, and foot, as in the following table:

MUSCLES OF THE GLUTEAL REGION.

Plantar Region.

1st Layer.
Abductor pollicis,
Abductor minimi digiti,
Flexor brevis digitorum.

2nd Layer.
Musculus accessorius,
Lumbricales.

3rd Layer.
Flexor brevis pollicis,
Adductor pollicis,
Flexor brevis minimi digiti,
Transversus pedis.

4th Layer.
Interossei plantares.

GLUTEAL REGION.

Gluteus maximus,
Gluteus medius,
Gluteus minimus,
Pyriformis,
Gemellus superior,

Obturator internus,
Gemellus inferior,
Obturator externus,
Quadratus femoris.

Dissection.—The subject being turned on its face, and a block placed beneath the os pubis to support the pelvis, the student commences the dissection of this region, by carrying an incision from the apex of the coccyx along the crest of the ilium to its anterior superior spinous process; or vice versa, if he be on the left side. He then makes an incision from the posterior fifth of the crest of the ilium, to the apex of the trochanter major, this marks the upper border of the gluteus maximus; and a third incision from the apex of the coccyx along the fleshy margin of the lower border of the gluteus maximus, to the outer side of the thigh, about four inches below the apex of the trochanter major. He then reflects the integument, superficial fascia, and deep fascia, which latter is very thin over this muscle, from the gluteus maximus, following rigidly the course of its fibres; and having exposed the muscle in its entire extent, he dissects the integument and superficial fascia from off the deep fascia which binds down the gluteus medius, the other portion of this region.

The Gluteus maximus (γλουτός, nates) is the thick, fleshy mass of muscle, of a quadrangular shape, which forms the convexity of the nates. In structure, it is extremely coarse, being made up of large fibres, which are collected into fasciculi, and these again into distinct muscular masses, separated by deep cellular furrows. It arises from the posterior fifth of the crest of the ilium, from the posterior surface of the sacrum and coccyx, and from the great sacro-ischiatic ligament. It passes obliquely outwards and downwards, to be inserted into the rough line leading from the trochanter major to the linea aspera, and is continuous by means of its tendon with the fascia lata covering the outer side of the thigh. A large bursa is situated between the broad tendon of this muscle and the femur.
Relations.—By its superficial surface with a thin aponeurotic fascia which separates it from the superficial fascia and integument, and with the vastus externus, a bursa being interposed. By its deep surface with the gluteus medius, pyriformis, gemelli, obturator internus, quadratus femoris, sacro-ischiatic foramina, great sacro-ischiatic ligament, tuberosity of the ischium, semi-membranosus, semi-tendinosus, biceps, and adductor magnus; the gluteal vessels and nerves, ischiatic vessels and nerves, and internal pudic vessels and nerve. By its upper border it overlaps the gluteus medius; and by the lower border forms the lower margin of the nates.

Fig. 103.*

The gluteus maximus must be turned down from its origin, in order to bring the next muscles into view.

The **GLUTEUS MEDius** is placed in front of, rather than beneath the gluteus maximus; and is covered in by a process of the deep fascia, which is very thick and dense. It *arises* from the outer lip of the crest of the ilium for four-fifths of its length, from the surface of bone between that border and the superior curved line on the dorsum ili, and from the dense fascia above mentioned. Its fibres converge to the outer part of the trochanter major, into which its tendon is *inserted*.

**Relations.**—By its superficial surface with the tensor vaginae femoris, gluteus maximus, and its fascia. By its deep surface with the gluteus minimus, and gluteal vessels and nerves. By its lower border with the pyriformis muscle. A bursa is interposed between its tendon and the upper part of the trochanter major.

This muscle should now be removed from its origin and turned down, so as to expose the next which is situated beneath it.

The **GLUTEUS MINimus** is a radiated muscle, *arising* from the surface of the dorsum ili, between the superior and inferior curved lines; its fibres converge to the anterior border of the trochanter major, into which it is *inserted* by means of a rounded tendon. There is no distinct line of separation between the gluteus medius and minimus anteriorly.

**Relations.**—By its superficial surface with the gluteus medius, and gluteal vessels. By its deep surface with the surface of the ilium, the long tendon of the rectus femoris, and the capsule of the hip-joint. A bursa is interposed between the tendon of the muscle and the trochanter.

The **PYRIFORMIS** muscle (pyrum, a pear, i. e. pear-shaped) *arises* from the anterior surface of the sacrum, by little slips that are interposed between the first and fourth anterior sacral foramina, and from the adjoining surface of the ilium. It passes out of the pelvis, through the great sacro-ischiatic foramen, and is *inserted* by a rounded tendon into the trochanteric fossa of the femur.

**Relations.**—By its superficial or external surface with the sacrum and gluteus maximus. By its deep or pelvic surface with the rectum, the sacral plexus of nerves, the branches of the internal iliac artery, the great sacro-ischiatic notch, and the capsule of the hip-joint. By its upper border with the gluteus medius and gluteal vessels and nerves. By its lower border with the gemellus superior, ischiatic, vessels and nerves, and internal pudic vessels and nerve.

The **Gemellus superior** (gemellus, double, twin,) is a small slip of muscle situated immediately below the pyriformis, it *arises* from the spine of the ischium, and is *inserted* into the upper border of the tendon of the obturator internus, and into the trochanteric fossa of the femur. The gemellus superior is not unfrequently wanting.

**Relations.**—By its superficial surface with the gluteus maximus, the
ischiatic vessels and nerves, and internal pudic vessels and nerve. By its deep surface with the pelvis, and capsule of the hip-joint.

The Obturator internus arises from the inner surface of the anterior wall of the pelvis, being attached to the margin of bone around the obturator foramen, and to the obturator membrane. It passes out of the pelvis through the lesser sacro-ischiatic foramen, and is inserted by a flattened tendon into the trochanteric fossa of the femur. The lesser sacro-ischiatic notch, over which this muscle plays as through a pulley, is faced with cartilage, and provided with a synovial bursa to facilitate its movements. The tendon of the obturator is supported on each side by the two gemelli muscles (hence their names), which are inserted into the sides of the tendon, and appear to be auxiliaries or superadded portions of the obturator internus.

Relations.—By its superficial or posterior surface with the internal pudic vessels and nerve, the obturator fascia, which separates it from the levator ani and viscera of the pelvis, the sacro-ischiatic ligaments, gluteus maximus, and ischiatic vessels and nerves. By its deep or anterior surface with the obturator membrane and the margin of bone surrounding it, the cartilaginous pulley of the lesser ischiatic foramen, the external surface of the pelvis, and the capsular ligament of the hip-joint. By its upper border, within the pelvis, with the obturator vessels and nerve; externally to the pelvis, with the gemellus superior. By its lower border with the gemellus inferior.

The Gemellus inferior arises from the posterior point of the tuberosity of the ischium, and is inserted into the lower border of the tendon of the obturator internus, and into the trochanteric fossa of the femur.

Relations.—By its superficial surface with the gluteus maximus, and ischiatic vessels and nerves. By its deep surface with the external surface of the pelvis, and capsule of the hip-joint. By its upper border with the tendon of the obturator internus. By its lower border with the tendon of the obturator externus and quadratus femoris.

In this region the tendon only of the obturator externus can be seen, situated deeply between the gemellus inferior and the upper border of the quadratus femoris. To expose this muscle fully, it is necessary to dissect it from the anterior part of the thigh, after the removal of the pectineus, adductor longus and adductor brevis muscles.

The Obturator externus muscle (obturare, to stop up) arises from the obturator membrane, and from the surface of bone immediately surrounding it anteriorly, viz. from the ramus of the os pubis and ischium: its tendon passes behind the neck of the femur, to be inserted with the external rotator muscles, into the trochanteric fossa of the femur.

Relations.—By its superficial or anterior surface with the tendon of the psoas and iliacus, pectineus, adductor brevis and magnus, the obturator vessels and nerve. By its deep or posterior surface with the obturator membrane and the margin of bone which surrounds
it, the lower part of the capsule of the hip-joint and the quadratus femoris.

The Quadratus femoris (square-shaped) arises from the external border of the tuberosity of the ischium, and is inserted into a rough line on the posterior border of the trochanter major, which is thence named linea quadrati.

Relations.—By its posterior surface with the gluteus maximus, and ischiatic vessels and nerves. By its anterior surface with the tendon of the obturator externus and trochanter minor, a synovial bursa often separating it from the latter. By its upper border with the gemellus inferior; and by the lower border with the adductor magnus.

Actions.—The glutei muscles are abductors of the thigh, when they take their fixed point from the pelvis. Taking their fixed point from the thigh, they steady the pelvis on the head of the femur; this action is peculiarly obvious in standing on one leg; they assist also in carrying the leg forward, in progression. The gluteus minimus being attached to the anterior border of the trochanter major, rotates the limb slightly inwards. The gluteus medius and maximus, from their insertion into the posterior aspect of the bone, rotate the limb outwards; the latter is, moreover, a tensor of the fascia of the thigh. The other muscles rotate the limb outwards, everting the knee and foot; hence they are named external rotators.

Anterior Femoral Region.

Tensor vaginae femoris,
Sartorius,
Rectus,
Vastus internus,
Vastus externus,
Crureus.

Dissection.—Make an incision along the line of Poupart’s ligament, from the anterior superior spinous process of the ilium to the spine of the os pubis; and a second, from the middle of the preceding down the inner side of the thigh, and across the inner condyle of the femur, to the head of the tibia, where it may be bounded by a transverse incision. Turn back the integument from the whole of this region, and examine the superficial fascia; which is next to be removed in the same manner. After the deep fascia has been well considered, it is likewise to be removed, by dissecting it off in the course of the fibres of the muscles. As it might not be convenient to the junior student to expose so large a surface at once as ordered in this dissection, the vertical incision may be crossed by one or two transverse incisions, as may be deemed most proper.

The Tensor vaginae femoris (stretcher of the sheath of the thigh) is a short flat muscle, situated on the outer side of the hip. It arises from the crest of the ilium, near its anterior superior spinous
process, and is inserted between two layers of the fascia lata at about one-fourth down the thigh.

Relations.—By its superficial surface with the fascia lata and integument. By its deep surface with the internal layer of the fascia lata, gluteus medius, rectus and vastus externus. By its inner border, near its origin with the sartorius.

The SARTORIUS (tailor’s muscle) is a long riband-like muscle, arising from the anterior superior spinous process of the ilium, and from the notch immediately below that process; it crosses obliquely the upper third of the thigh, descends behind the inner condyle of the femur, and is inserted by an aponeurotic expansion into the inner tuberosity of the tibia. This expansion covers in the insertion of the tendons of the gracilis and semitendinosus muscles. The inner border of the sartorius muscle is the guide to the operation for tying the femoral artery in the middle of its course.

Relations.—By its superficial surface with the fascia lata and some cutaneous nerves. By its deep surface with the psoas and iliacus, rectus, sheath of the femoral vessels and saphenous nerves, vastus internus, adductor longus, adductor magnus, gracilis, long saphenous nerve, internal lateral ligament of the knee-joint. By its expanded insertion with the tendons of the gracilis and semitendinosus, a synovial bursa being interposed. At the knee-joint its posterior border is in relation with the internal saphenous vein. At the upper third of the thigh the sartorius forms, with the lower border of the adductor

longus, an isosceles triangle, whereof the base corresponds with Pou-
part's ligament. A perpendicular line, drawn from the middle of the 
base to the apex of this triangle, immediately overlies the femoral 
artery with its sheath.

The Rectus (straight) muscle is fusiform in its shape and bipenni-
form in the disposition of its fibres. It arises by two round tendons, 
one from the anterior inferior spinous process of the ilium, the other 
from the upper lip of the acetabulum; and is inserted by a broad and 
strong tendon, into the upper border of the patella. It is more correct 
to consider the patella as a sesamoid bone, developed within the 
tendon of the rectus; and the ligamentum patellæ as the continuation 
of the tendon to its insertion into the tubercle of the tibia.

Relations.—By its superficial surface with the gluteus medius, psoas 
and iliacus, sartorius; and, for the lower three-fourths of its extent, 
with the fascia lata. By its deep surface with the capsule of the hip-
joint, the external circumflex vessels, crureus, and vastus internus 
and externus.

The rectus must now be divided through its middle, and the two 
ends turned aside, to bring clearly into view the next muscles.

The three next muscles are generally considered collectively under 
the name of triceps extensor crus. Adopting this view, the muscle 
surrounds the whole of the femur, excepting the rough line (linea 
aspera) upon its posterior aspect. Its division into three parts is not 
well defined; the fleshy mass upon each side being distinguished by 
the names of vastus internus and externus, the middle portion by that 
of crureus.

The Vastus externus, narrow below and broad above, arises 
from the outer border of the patella, and is inserted into the femur 
and outer side of the linea aspera, as high as the base of the trochanter 
major.

Relations.—By its superficial surface with the fascia lata, rectus, 
biceps, semi-membranosus and gluteus maximus, a synovial bursa 
being interposed between it and the latter. By its deep surface with 
the crureus and femur.

The Vastus internus, broad below and narrow above, arises 
from the inner border of the patella, and is inserted into the femur 
and inner side of the linea aspera as high up as the anterior intertro-
chanteric line.

Relations.—By its superficial surface with the psoas and iliacus, 
rectus, sartorius, femoral artery and vein and saphenous nerves, pecti-
neus, adductor longus, brevis, and magnus, and fascia lata. By its 
deep surface with the crureus and femur.

The Crureus (crus, the leg) arises from the upper border of the 
patella, and is inserted into the front aspect of the femur, as high as 
the anterior intertrochanteric line. When the crureus is divided from 
its insertion, a small muscular fasciculus is often seen upon the lower 
part of the femur, which is inserted into the pouch of synovial mem-
brane, that extends upwards from the knee-joint, behind the patella.
This is named, from its situation, sub-crureus, and would seem to be intended to support the synovial membrane. 

_Relations._—By its _superficial surface_ with the external circumflex vessels, the rectus, vastus internus and externus. By its _deep surface_ with the femur, the sub-crureus, and synovial membrane of the knee-joint.

_Actions._—The tensor vaginae femoris renders the fascia lata tense, and slightly inverts the limb. The sartorius flexes the leg upon the thigh, and, continuing to act, the thigh upon the pelvis, at the same time carrying the leg across that of the opposite side, into the position in which tailors sit; hence its name. Taking its fixed point from below, it assists the extensor muscles in steadying the leg, for the support of the trunk. The other four muscles have been collectively named _quadriceps extensor_, from their similarity of action. They extend the leg upon the thigh, and obtain a great increase of power by their attachment to the patella, which acts as a fulcrum. Taking their fixed point from the tibia, they steady the femur upon the leg, and the rectus, by being attached to the pelvis, serves to balance the trunk upon the lower extremity.

_Internal Femoral Region._

Iliacus internus,  
Psoas magnus,  
Pectineus,  
Adductor longus,  
Adductor brevis,  
Adductor magnus,  
Gracilis.

_Dissection._—These muscles are exposed by the removal of the inner flap of integument recommended in the dissection of the anterior femoral region. The iliacus and psoas arising from within the abdomen can only be seen in their entire extent after the removal of the viscera from that cavity.

The _Iliacus internus_ is a flat radiated muscle. It _arises_ from the whole extent of the inner concave surface of the ilium; and, after joining with the tendon of the psoas, is _inserted_ into the trochanter minor of the femur. A few fibres of this muscle are derived from the base of the sacrum, and others from the capsular ligament of the hip-joint.

_Relations._—By its _anterior surface_, within the pelvis, with the external cutaneous nerve, and with the iliac fascia, which separates the muscle from the peritoneum, on the right from the caecum, and on the left from the sigmoid flexure of the colon; _externally_ to the pelvis with the fascia lata, rectus, and sartorius. By its _posterior surface_ with the iliac fossa, margin of the pelvis, and with the capsule of the hip-joint, a synovial bursa of large size being interposed, which is sometimes
continuous with the synovial membrane of the articulation. By its inner border with the psoas magnus and crural nerve.

The Psoas magnus (ψώας, lumbus, a loin), situated by the side of the vertebral column in the loins, is a long fusiform muscle. It arises from the intervertebral substances, part of the bodies and bases of the transverse processes, and from a series of tendinous arches, thrown across the constricted portion of the last dorsal and four upper lumbar vertebrae. These arches are intended to protect the lumbar arteries and sympathetic filaments of nerves from pressure, in their passage beneath the muscle. From this extensive origin the muscle passes along the margin of the brim of the pelvis, and beneath Poupart’s ligament, to its insertion. The tendon of the psoas magnus unites with that of the iliacus, and the conjoined tendon is inserted into the posterior part of the trochanter minor, a bursa being interposed.

Relations.—By its anterior surface with the ligamentum arcuatum internum of the diaphragm, the kidney, the psoas parvus, genito-crural nerve, sympathetic nerve, its proper fascia, the peritoneum and colon, and along its pelvic border with the common and external iliac artery and vein. By its posterior surface with the lumbar vertebrae, the lumbar arteries, quadratus lumborum, from which it is separated by the anterior layer of the aponeurosis of the transversalis, and with the crural nerve, which near Poupart’s ligament gets to its outer side. The lumbar plexus of nerves is situated in the substance of the posterior part of the muscle. In the thigh the muscle is in relation with the fascia lata in front; the border of the pelvis and hip-joint, from which it is separated by the synovial membrane, common to it and the preceding muscle, behind; with the crural nerve, and iliacus to the outer side; and with the femoral artery, by which it is slightly overlaid to the inner side.

The Pectineus is a flat and quadrangular muscle; it arises from the pectineal line (pecten, a crest) of the os pubis, and from the surface of bone in front of that bone. It is inserted into the line leading from the anterior intertrochanteric line to the linea aspera of the femur.

Relations.—By its anterior surface with the pubic portion of the fascia lata, which separates it from the femoral artery and vein and internal saphenous vein, and lower down with the profunda artery. By its posterior surface with the capsule of the hip-joint, and with the obturator externus and adductor brevis, the obturator vessels being interposed. By its external border with the psoas, the femoral artery resting upon the line of interval. By its internal border with the outer edge of the adductor longus. Obturator hernia is situated directly behind this muscle, which forms one of its coverings.

The Adductor longus (adducere, to draw to), the most superficial of the three adductors, arises by a round and thick tendon from the front surface of the os pubis, immediately below the angle; and, assuming a flattened and expanded form as it descends, is inserted into the middle third of the linea aspera.
Relations.—By its anterior surface with the pubic portion of the fascia lata, and near its insertion with the femoral artery and vein. By its posterior surface with the adductor brevis and magnus, the anterior branches of the obturator vessels and nerves, and near its insertion with the profunda artery and vein. By its outer border with the pectineus, and by the inner border with the gracilis.

The pectineus must be divided near its origin and turned outwards, and the adductor longus through its middle, turning its ends to either side, to bring into view the adductor brevis.

The Adductor brevis, placed beneath the pectineus and adductor longus, is fleshy, and thicker than the adductor longus; it arises from the body and ramus of the os pubis, and is inserted into the upper third of the linea aspera.

Relations.—By its anterior surface with the pectineus, adductor longus, and anterior branches of the obturator vessels and nerve. By its posterior surface with the adductor magnus, and posterior branches of the obturator vessels and nerve. By its outer border with the obturator externus, and conjoined tendon of the psoas and iliacus. By its inner border with the gracilis and adductor magnus. The adductor brevis is pierced near its insertion by the middle perforating artery.

The adductor brevis may now be divided from its origin and turned outwards, or its inner two thirds may be cut away entirely, when the adductor magnus muscle will be exposed in its entire extent.

The Adductor magnus is a broad triangular muscle, forming a septum of division between the muscles situated on the anterior and those on the posterior aspect of the thigh. It arises by fleshy fibres from the ramus of the pubes and ischium and from the side of the tuber ischii; and radiating in its passage outwards is inserted into the whole length of the linea aspera, and inner condyle of the femur. The adductor magnus is pierced by five openings: the three superior, for the three perforating arteries; and the fourth, for the termination of the profunda. The fifth is the large oval opening, in the tendinous portion of the muscle, that gives passage to the femoral vessels.

Relations.—By its anterior surface with the pectineus, adductor brevis, adductor longus, femoral artery and vein, profunda artery and vein, with their branches, and with the posterior branches of the obturator vessels and nerve. By its posterior surface with the semi-tendinosus, semi-membranosus, biceps, and gluteus maximus. By its inner border with the gracilis and sartorius. By its upper border with the obturator externus, and quadratus femoris.

The Gracilis (slender) is situated along the inner border of the thigh. It arises by a broad but very thin tendon, from the body of the os pubis along the edge of the symphysis and from the margin of the ramus of the pubes and ischium; and is inserted by a rounded tendon into the inner tuberosity of the tibia, beneath the expansion of the sartorius.

Relations.—By its inner or superficial surface with the fascia lata, and below with the sartorius and internal saphenous nerve; the in-
ternal saphenous vein crosses it lying superficially to the fascia lata. By its outer or deep surface with the adductor longus, brevis, and magnus, and the internal lateral ligament of the knee-joint, from which it is separated by a synovial bursa common to the tendons of the gracilis and semi-tendinosus.

**Actions.**—The iliacus, psoas, pectineus, and adductor longus muscles bend the thigh upon the pelvis, and, at the same time, from the obliquity of their insertion into the lesser trochanter and linea aspera, rotate the entire limb outwards; the pectineus and adductors adduct the thigh powerfully; and from the manner of their insertion into the linea aspera, they assist in rotating the limb outwards. The gracilis is likewise an adductor of the thigh; but contributes also to the flexion of the leg, by its attachment to the inner tuberosity of the tibia.

**Posterior Femoral Region.**

Biceps,
Semi-tendinosus,
Semi-membranosus.

**Dissection.**—Remove the integument and fascia on the posterior part of the thigh by two flaps, as on the anterior region, and turn aside the gluteus maximus from the upper part; the muscles may then be examined.

The Biceps femoris (bis, double, ὀψαλλός, head) arises by two heads, one by a common tendon with the semi-tendinosus; the other muscular and much shorter, from the lower two thirds of the external border of the linea aspera. This muscle forms the outer hamstring, and is inserted by a strong tendon into the head of the fibula; a portion of the tendon is continued downwards into the fascia of the leg, and another is attached to the outer tuberosity of the tibia.

**Relations.**—By its superficial or posterior surface with the gluteus maximus and fascia lata. By its deep or anterior surface with the semi-membranosus, adductor magnus, vastus externus, the great sciatic nerve, popliteal artery and vein, and near its insertion with the external head of the gastrocnemius, and plantaris. By its inner border with the semi-tendinosus, and in the popliteal space with the popliteal artery and vein.

The Semi-tendinosus, remarkable for its long tendon, arises in common with the long head of the biceps, from the tuberosity of the ischium; the two muscles being closely united for several inches below their origin. It is inserted into the inner tuberosity of the tibia.

**Relations.**—By its superficial surface with the gluteus maximus, fascia lata, and at its insertion with the synovial bursa which separates its tendon from the expansion of the sartorius. By its deep surface with the semi-membranosus, adductor magnus, internal head of the gastrocnemius, and internal lateral ligament of the knee-joint, the synovial bursa common to it and the tendon of the gracilis being inter-
Fig. 105.*

By its inner border with the gracilis; and by its outer border with the biceps.

These two muscles must be dissected from the tuberosity of the ischium, to bring into view the origin of the next.

The Semi-membranosus, remarkable for the tendinous expansion upon its anterior and posterior surface, arises from the tuberosity of the ischium, in front of the common origin of the two preceding muscles. It is inserted into the posterior part of the inner tuberosity of the tibia; at its insertion the tendon splits into three portions, one of which is inserted in a groove on the inner side of the head of the tibia, beneath the internal lateral ligament. The second is continuous with an aponeurotic expansion that binds down the popliteus muscle, the popliteal fascia; and the third turns upwards and outwards to the external condyle of the femur, forming the middle portion of the posterior ligament of the knee-joint (ligamentum posticum Winslowii).

The tendons of the last two muscles viz. the semi-tendinosus and semi-membranosus, with those of the gracilis and sartorius, form the inner ham-string.

Relations. — By its superficial surface with the gluteus maximus, biceps, semi-tendinosus, fascia lata, and at its insertion with the tendinous expansion of the sartorius. By its deep surface with the quadratus femoris, adductor magnus, in-

The tendon of the biceps forms the outer hamstring; and the sartorius with the tendons of the gracilis, semi-tendinosus, and semi-membranosus, the inner hamstring.
ternal head of the gastrocnemius, the knee-joint from which it is separated by a synovial membrane, and the popliteal artery and vein. By its inner border with the gracilis. By its outer border with the great ischiatic nerve, and in the popliteal space with the popliteal artery and vein.

If the semi-membranosus muscle be turned down from its origin, the student will bring into view the broad and radiated expanse of the adductor magnus, upon which the three flexor muscles above described rest.

Actions.—These three hamstring muscles are the direct flexors of the leg upon the thigh; and, by taking their origin from below, they balance the pelvis on the lower extremities. The biceps, from the obliquity of its direction, everts the leg when partly flexed, and the semi-tendinosus turns the leg inwards when in the same state of flexion.

Anterior Tibial Region.

Tibialis anticus,
Extensor longus digitorum,
Peroneus tertius,
Extensor proprius pollicis.

Dissection.—The dissection of the anterior tibial region is to be commenced by carrying an incision along the middle of the leg, midway between the tibia and the fibula, from the knee to the ankle, and bounding it inferiorly by a transverse incision extending from one malleolus to the other. And to expose the tendons on the dorsum of the foot, the longitudinal incision may be carried onwards to the outer side of the base of the great toe, and be terminated by another incision directed across the heads of the metatarsal bones.

The Tibialis anticus muscle (flexor tarsi tibialis) arises from the upper two-thirds of the tibia, from the interosseous membrane, and from the deep fascia; its tendon passes through a distinct sheath in the annular ligament, and is inserted into the inner side of the internal cuneiform bone, and base of the metatarsal bone of the great toe.

Relations.—By its anterior surface with the deep fascia, from which many of its superior fibres arise, and with the anterior annular ligament. By its posterior surface with the interosseous membrane, tibia, ankle-joint, and bones of the tarsus with their articulations. By its internal surface with the tibia. By the external surface with the extensor longus digitorum, extensor proprius pollicis, and the anterior tibial vessels and nerve.

The Extensor longus digitorum arises from the head of the tibia, from the upper three-fourths of the fibula, from the interosseous membrane, and from the deep fascia. Below, it divides into four tendons, which pass beneath the annular ligament, to be inserted into the second and third phalanges of the four lesser toes. The mode of insertion of the extensor tendons, both in the hand and in the foot, is
remarkable, each tendon spreads into a broad aponeurosis over the first phalanx; this aponeurosis divides into three slips, the middle one is inserted into the base of the second phalanx, and the two lateral slips are continued onwards, to be inserted into the base of the third.

Relations.—By its anterior surface with the deep fascia of the leg and foot, and with the anterior annular ligament. By its posterior surface with the interosseous membrane, fibula, ankle-joint, extensor brevis digitorum which separates its tendons from the tarsus, and with the metatarsus and phalanges. By its inner surface with the tibialis anticus, extensor proprius pollicis, and anterior tibial vessels. By its outer border with the peroneus longus and brevis.

The PERONEUS TERTIUS (flexor tarsi fibularis) arises from the lower fourth of the fibula, and is inserted into the base of the metatarsal bone of the little toe. Although apparently but a mere division or continuation of the extensor longus digitorum, this muscle may be looked upon as analogous to the flexor carpi ulnaris of the fore-arm. Sometimes it is altogether wanting.

The EXTENSOR PROPRIUS POLLICIS lies between the tibialis anticus and extensor longus digitorum. It arises from the lower two-thirds of the fibula and interosseous membrane. Its tendon passes through a distinct sheath in the annular ligament, and is inserted into the base of the last phalanx of the great toe.

* The muscles of the anterior tibial region. 1. The extensor muscles inserted into the patella. 2. The subcutaneous surface of the tibia. 3. The tibialis anticus. 4. The extensor longus digitorum. 5. The extensor proprius pollicis. 6. The peroneus tertius. 7. The peroneus longus. 8. The peroneus brevis. 9, 9. The borders of the soleus muscle. 10. A part of the inner belly of the gastrocnemius. 11. The extensor brevis digitorum; the tendon in front of this number is that of the peroneus tertius; and that behind it, the tendon of the peroneus brevis.
Relations.—By its anterior surface with the deep fascia of the leg and foot, and with the anterior annular ligament. By its posterior surface with the interosseous membrane, the fibula, the tibia, the ankle-joint, the extensor brevis digitorum, and the bones and articulations of the great toe. It is crossed upon this aspect by the anterior tibial vessels and nerve. By its outer side with the extensor longus digitorum, and in the foot with the dorsalis pedis artery and veins; the outer side of its tendon upon the dorsum of the foot being the guide to these vessels. By its inner side with the tibialis anticus, and with the anterior tibial vessels.

Actions.—The tibialis anticus and peroneus tertius are direct flexors of the tarsus upon the leg; acting in conjunction with the tibialis posticus they direct the foot inwards, and with the peroneus longus and brevis outwards. They assist also in preserving the flatness of the foot during progression. The extensor longus digitorum and extensor proprius pollicis, are direct extensors of the phalanges; but, continuing their action, they assist the tibialis anticus and peroneus tertius, in flexing the entire foot upon the leg. Taking their origin from below, they increase the stability of the ankle-joint.

Posterior Tibial Region.

Superficial Group.

Gastrocnemius,
Plantaris,
Soleus.

Dissection.—Make an incision from the middle of the popliteal

* The superficial muscles of the posterior aspect of the leg, 1. The biceps muscle, forming the outer hamstring. 2. The tendons forming the inner hamstring. 3. The popliteal space. 4. space down the middle of the posterior part of the leg to the heel, bounding it inferiorly by a transverse incision passing between the two malleoli. Turn aside the flaps of integument and remove the fasciae from the whole of this region; the gastrocnemius muscle will then be exposed.

The **Gastrocnemius** (γαστρόκενθήμον, the bellied part of the leg) arises by two heads from the two condyles of the femur, the inner head being the longest. They unite to form the beautiful muscle so characteristic of this region of the limb. It is inserted, by means of the tendo Achillis, into the lower part of the posterior tuberosity of the os calcis, a synovial bursa being placed between that tendon and the upper part of the tuberosity. The gastrocnemius must be removed from its origin, and turned down, in order to expose the next muscle.

**Relations.**—By its superficial surface with the deep fascia of the leg which separates it from the external saphenous vein, and with the external saphenous nerve. By its deep surface with the lateral portions of the posterior ligament of the knee-joint, the popliteus, plantaris, and soleus. The internal head of the muscle rests against the posterior surface of the internal condyle of the femur; the external head against the outer side of the external condyle. In the latter a sesamoid bone is sometimes found.

The **Plantaris** (planta, the sole of the foot), an extremely diminutive muscle situated between the gastrocnemius and soleus, arises from the outer condyle of the femur; and is inserted, by its long and delicately slender tendon, into the inner side of the posterior tuberosity of the os calcis, by the side of the tendo Achillis; having crossed obliquely between the two muscles.

The **Soleus** (solea, a sole), is the broad muscle upon which the plantaris rests. It arises from the head and upper third of the fibula, from the oblique line and middle third of the tibia. Its fibres converge to the tendo Achillis, by which it is inserted into the posterior tuberosity of the os calcis. Between the fibular and tibial origins of this muscle is a tendinous arch, beneath which the popliteal vessels and nerve pass into the leg.

**Relations.**—By its superficial surface with the gastrocnemius and plantaris. By its deep surface with the intermuscular fascia, which separates it from the flexor longus digitorum, tibialis posticus, flexor longus pollicis, from the posterior tibial vessels and nerve, and from the peroneal vessels.

**Actions.**—The three muscles of the calf draw powerfully on the os calcis, and lift the heel; continuing their action, they raise the entire body. This action is attained by means of a lever of the second power, the fulcrum (the toes) being at one end, the weight (the body supported on the tibia) in the middle, and the power (these muscles) at the other extremity.

They are, therefore, the walking muscles, and perform all movements that require the support of the whole body from the ground, as
dancing, leaping, &c. Taking their fixed point from below, they steady the leg upon the foot.

Deep Layer.

Popliteus,
Flexor longus pollicis,
Flexor longus digitorum,
Tibialis posticus.

Dissection.—After the removal of the soleus, the deep layer will be found bound down by an intermuscular fascia which is to be dissected away; the muscles may then be examined.

The Popliteus muscle (poples, the ham of the leg), forms the floor of the popliteal region at its lower part, and is bound tightly down by a strong fascia derived from the middle slip of the tendon of the semimembranosus muscle. It arises by a rounded tendon from a deep groove on the outer side of the external condyle of the femur, beneath the external lateral ligament; and spreading obliquely over the head of the tibia, is inserted into the surface of bone above its oblique line. This line is called, from being the limit of insertion of the popliteus muscle, the popliteal line.

Relations.—By its superficial surface with a thick fascia which separates it from the two heads of the gastrocnemius, the plantaris, and the popliteal vessels and nerve. By its deep surface with the synovial membrane of the knee-joint and with the upper part of the tibia.

The Flexor Longus Pollicis is the most superficial of the next three muscles. It arises from the lower two-thirds of the fibula, and passes through a groove in the astragalus and os calcis, which is converted by tendinous fibres into a distinct sheath lined by a synovial membrane, into the sole of the foot; it is inserted into the base of the last phalanx of the great toe.

Relations.—By its superficial surface with the intermuscular fascia, which separates it from the soleus and tendo Achillis. By its deep surface with the tibialis posticus, fibula, fibular vessels, interosseous membrane, and ankle-joint. By its outer border with the peroneus longus and brevis. By its inner border with the flexor longus digitorum. In the foot, the tendon of the flexor longus pollicis is connected with that of the flexor longus digitorum by a short tendinous slip.

The Flexor Longus Digitorum (perforans) arises from the surface of the tibia, immediately below the popliteal line. Its tendon passes through a sheath common to it and the tibialis posticus behind the inner malleolus; it then passes through a second sheath which is connected with a groove in the astragalus and os calcis, into the sole of the foot, where it divides into four tendons, which are inserted into the base of the last phalanx of the four lesser toes, perforating the tendons of the flexor brevis digitorum.

Relations.—By its superficial surface with the intermuscular fascia, which separates it from the soleus, and with the posterior tibial vessels
and nerve. By its deep surface with the tibia and tibialis posticus. In the sole of the foot its tendon is in relation with the abductor pollicis and flexor brevis digitorum, which lie superficially to it, and it crosses the tendon of the flexor longus pollicis. At the point of crossing it receives the tendinous slip of communication from the latter.

The flexor longus pollicis must now be removed from its origin, and the flexor longus digitorum drawn aside, to bring into view the entire extent of the tibialis posticus.

The Tibialis posticus (extensor tarsi tibialis) lies upon the interosseous membrane, between the two bones of the leg. It arises by two heads from the adjacent sides of the tibia and fibula their whole length, and from the interosseous membrane. Its tendon passes inwards beneath the tendon of the flexor longus digitorum, and runs in the same sheath; it then passes through a proper sheath over the deltoid ligament, and beneath the calcaneo-scaphoid articulation, to be inserted into the tuberosity of the scaphoid and internal cuneiform bone. While in the common sheath behind the internal malleolus, the tendon of the tibialis posticus lies internally to that of the flexor longus digitorum, from which it is separated by a thin fibrous partition. A sesamoid bone is usually met with in the tendon close to its insertion.

Relations.—By its superficial surface with the intermuscular septum, the

* The deep layer of muscles of the posterior tibial region. 1. The lower extremity of the femur. 2. The ligamentum posticum Winslowii. 3. The tendon of the semi-membranosus muscle dividing into its three slips. 4. The internal lateral ligament of the knee-joint. 5. The external lateral ligament. 6. The popliteus muscle. 7. The flexor longus digitorum. 8. The tibialis posticus. 9. The flexor longus pollicis. 10. The peroneus longus muscle. 11. The peroneus brevis. 12. The tendo Achillis divided near its insertion into the os calcis. 13. The tendons of the tibialis posticus and flexor longus digitorum muscles, just as they are about to pass beneath the internal annular ligament of the ankle; the interval between the latter tendon and the tendon of the flexor longus pollicis is occupied by the posterior tibial vessels and nerve.
flexor longus pollicis, flexor longus digitorum, posterior tibial vessels and nerve, peroneal vessels, and in the sole of the foot with the abductor pollicis. By its deep surface with the interosseous membrane, the fibula and tibia, the ankle joint, and the astragalus. The anterior tibial artery passes between the two heads of the muscle.

The student will observe that the two latter muscles change their relative position to each other in their course. Thus, in the leg, the position of the three muscles from within outwards, is, flexor longus digitorum, tibialis posticus, flexor longus pollicis. At the inner malleolus, the relation of the tendons is, tibialis posticus, flexor longus digitorum, both in the same sheath; then a broad groove, which lodges the posterior tibial artery, venae comites, and nerve; and lastly, the flexor longus pollicis.

Actions.—The popliteus is a flexor of the tibia upon the thigh, carrying it at the same time inwards so as to invert the leg. The flexor longus pollicis, and flexor longus digitorum are the long flexors of the toes; their tendons are connected in the foot by a short tendinous band, hence they necessarily act together. The tibialis posticus is an extensor of the tarsus upon the leg, and an antagonist to the tibialis anticus. It combines with the tibialis anticus in adduction of the foot.

Fibular Region.

Peroneus longus.
Peroneus brevis.

Dissection.—These muscles are exposed by continuing the dissection of the anterior tibial region outwards beyond the fibula, to the border of the posterior tibial region.

The Peroneus longus (πρόπος, fibula, extensor tarsi fibularis longior) muscle arises from the head and upper third of the outer side of the fibula, and terminates in a long tendon, which passes behind the external malleolus, and obliquely across the sole of the foot, through the groove in the cuboid bone, to be inserted into the base of the metatarsal bone of the great toe. Its tendon is thickened where it glides behind the external malleolus, and a sesamoid bone is developed in that part which plays upon the cuboid bone.

Relations.—By its superficial surface with the fascia of the leg and foot. By its deep surface with the fibula, peroneus brevis, os calcis, and cuboid bone, and near the head of the fibula with the fibular nerve. By its anterior border it is separated from the extensor longus digitorum by the attachment of the fascia of the leg to the fibula; and by the posterior border by the same medium from the soleus and flexor longus pollicis. The peroneus longus is furnished with three tendinous sheaths and as many synovial membranes; the first is situated behind the external malleolus, and is common to this muscle and the peroneus brevis, the second on the outer side of the os calcis, and the third on the cuboid bone.

The Peroneus brevis (extensor tarsi fibularis brevior) lies be-
neath the peroneus longus; it arises from the lower half of the fibula, and terminates in a tendon which passes behind the external malleolus and through a groove in the os calcis, to be inserted into the base of the metatarsal bone of the little toe.

*Relations.*—By its superficial surface with the peroneus longus and fascia of the leg and foot. By its deep surface with the fibula, the os calcis, and cuboid bone. The lateral relations are the same as those of the peroneus longus. The tendon of the peroneus brevis has but two tendinous sheaths and two synovial membranes, one behind the external malleolus and common to both peronei, the other upon the side of the os calcis.

*Actions.*—The peronei muscles are extensors of the foot, conjointly with the tibialis posticus. They antagonise the tibialis anticus and peroneus tertius, which are flexors of the foot. The whole of these muscles acting together, tend to maintain the flatness of the foot, so necessary to security in walking.

**Foot.**

**Dorsal Region.**

*Extensor brevis digitorum,*

*Interossei dorsales.*

The Extensor brevis digitorum muscle arises from the outer side of the os calcis, crosses the foot obliquely, and terminates in four tendons, the innermost of which is inserted into the base of the first phalanx of the great toe, and the other three into the sides of the long extensor tendons of the second, third, and fourth toes.

*Relations.*—By its upper surface with the tendons of the extensor longus digitorum, peroneus brevis, and with the deep fascia of the foot. By its under surface with the tarsal and metatarsal bones. Its inner border is in relation with the dorsalis pedis artery, and the innermost tendon of the muscle crosses that artery just before its division.

The Dorsal interossei muscles are placed between the metatarsal bones; they resemble the analogous muscles in the hand in arising by two heads from the adjacent sides of the metatarsal bones; their tendons are inserted into the base of the first phalanx, and into the digital expansion of the tendons of the long extensor.

The first dorsal interosseous is inserted into the inner side of the second toe, and is therefore an adductor; the other three are inserted into the outer side of the second, third, and fourth toes, and are consequently abductors.

*Relations.*—By their upper surface with a strong fascia which separates them from the extensor tendons. By their under surface with the plantar interossei. Each of the muscles gives passage to a small artery (posterior perforating) which communicates with the external plantar artery. And between the heads of the first interosseous muscle the communicating artery of the dorsalis pedis takes its course.
ABDUCTOR POLLICIS.

Plantar Region.

First Layer.

Abductor pollicis,
Abductor minimi digiti,
Flexor brevis digitorum.

Dissection.—The sole of the foot is best dissected by carrying an incision around the heel, and along the inner and outer borders of the foot, to the great and little toes. This incision should divide the integument and superficial fascia, and both together should be dissected from the deep fascia, as far forward as the base of the phalanges, where they may be removed from the foot altogether. The deep fascia should then be removed, and the first layer of muscles will be brought into view.

The Abductor pollicis lies along the inner border of the foot; it arises by two heads, between which the tendons of the long flexors, arteries, veins, and nerves enter the sole of the foot. One head arises from the inner tuberosity of the os calcis, the other from the internal annular ligament and plantar fascia. Insertion, into the base of the first phalanx of the great toe, and into the internal sesamoid bone.

Relations.—By its superficial surface with the internal portion of the plantar fascia. By its deep surface with the flexor brevis pollicis, musculus accessorius, tendons of the flexor longus digitorum and flexor longus pollicis, tendons of the tibialis anticus and posticus, the plantar vessels and nerves, and the tarsal bones. On its outer border with the flexor brevis digitorum, from which it is separated by a vertical septum of the plantar fascia.

* The first layer of muscles in the sole of the foot; this layer is exposed by the removal of the plantar fascia. 1. The os calcis. 2. The posterior part of the plantar fascia divided transversely. 3. The abductor pollicis. 4. The abductor minimi digiti. 5. The flexor brevis digitorum. 6. The tendon of the flexor longus pollicis muscle. 7. The lumbricales. On the second and third toes, the tendons of the flexor longus digitorum are seen passing through the bifurcation of the tendons of the flexor brevis digitorum.
The Abductor Minimi Digitii lies along the outer border of the sole of the foot. It arises from the outer tuberosity of the os calcis, and from the plantar fascia, as far forward as the base of the fifth metatarsal bone, and is inserted into the base of the first phalanx of the little toe.

Relations.—By its superficial surface with the external portion of the plantar fascia. By its deep surface with the musculus accessorius, flexor brevis minimi digitii, with the tarsal bones, and with the metatarsal bone of the little toe. By its inner side with the flexor brevis digitorum, from which it is separated by the vertical septum of the plantar fascia.

The Flexor Brevis Digitorum (perforatus) is placed between the two preceding muscles. It arises from the under surface of the os calcis, from the plantar fascia and intermuscular septa, and is inserted by four tendons into the base of the second phalanx of the four lesser toes. Each tendon divides, previously to its insertion, to give passage to the tendon of the long flexor; hence its cognomen perforatus.

Relations.—By its superficial surface with the plantar fascia. By its deep surface with a thin layer of fascia which separates it from the musculus accessorius, tendons of the flexor longus digitorum and flexor longus pollicis, and plantar vessels and nerves. By its borders with the vertical septa of the plantar fascia, which separate the muscle, on the one side from the abductor pollicis, and on the other from the abductor minimi digitii.

Second Layer.
Musculus accessorius, Lumbricales.

Dissection. — The three preceding muscles must be divided from their origin, and anteriorly through their tendons, and removed, in order to bring into view the second layer.

* The third and a part of the second layer of muscles of the sole of the foot. 1. The divided edge of the plantar fascia. 2. The musculus accessorius. 3. The tendon of the flexor longus digitorum. 4. The tendon of the flexor longus pollicis. 5. The flexor brevis pollicis. 6. The adductor pollicis. 7. The flexor brevis minimi digitii. 8. The transversus pedis. 9. Interossei muscles, plantar and dorsal. A convex ridge formed by the tendon of the peroneus longus muscle in its oblique course across the foot.
The Musculus accessorius arises by two slips from either side of the under surface of the os calcis; the inner slip being fleshy, the outer tendinous. The muscle is inserted into the outer side and upper surface of the tendon of the flexor longus digitorum.

Relations.—By its superficial surface with the three muscles of the superficial layer, from which it is separated by their fascial sheaths, and with the external plantar vessels and nerves. By its deep surface with the under surface of the os calcis and the long calcaneo-cuboid ligament.

The Lumbricales (lumbricus, an earthworm) are four little muscles arising from the tibial side of the tendons of the flexor longus digitorum, and inserted into the expansion of the extensor tendons, and into the base of the first phalanx of the four lesser toes.

Relations.—By their superficial surface with the tendons of the flexor brevis digitorum. By their deep surface with the third layer of muscles of the sole of the foot. They pass between the digital slips of the deep fascia to reach their insertion.

Third Layer.

Flexor brevis pollicis,
Abductor pollicis,
Flexor brevis minimi digiti,
Transversus pedis.

Dissection.—The tendons of the long flexors and the muscles connected with them must be removed, to see clearly the attachments of the third layer.

The Flexor brevis pollicis arises by a pointed tendinous process from the side of the cuboid, and from the external cuneiform bone; it is inserted by two heads into the base of the first phalanx of the great toe. Two sesamoid bones are developed in the tendons of insertion of these two heads, and the tendon of the flexor longus pollicis lies in the groove between them.

Relations.—By its superficial surface with the abductor pollicis, tendon of the flexor longus pollicis, and plantar fascia. By its deep surface with the tarsal bones and their ligaments, the metatarsal bone of the great toe, and the insertion of the tendon of the peroneus longus. By its inner border with the abductor pollicis; and by its outer border with the adductor pollicis; with both of these muscles it is blended near its insertion.

The Adductor pollicis arises from the cuboid bone, from the sheath of the tendon of the peroneus longus, and from the base of the third and fourth metatarsal bones. It is inserted into the base of the first phalanx of the great toe.

Relations.—By its superficial surface with the tendons of the flexor longus and flexor brevis digitorum, the musculus accessorius, and lumbricales. By its deep surface with the tarsal bones and ligaments,
the external plantar artery and veins, the interossei muscles, tendon of
the peroneus longus, and metatarsal bone of the great toe. By its
inner border with the flexor brevis pollicis; with which its fibres are
blended.

The **Flexor brevis minimi digiti** arises from the base of the
metatarsal bone of the little toe, and from the sheath of the tendon of
the peroneus longus. It is inserted into the base of the first phalanx
of the little toe.

*Relations.* By its superficial surface with the tendons of the flexor
longus and flexor brevis digitorum, the fourth lumbricalis, abductor
minimi digiti, and plantar fascia. By its deep surface with the plan-
tar interosseous muscle of the fourth metatarsal space, and the meta-
tarsal bone.

The **Transversus pedis** arises by fleshy slips, from the heads of
the metatarsal bones of the four lesser toes. Its tendon is inserted
into the base of the first phalanx of the great toe, being blended with
that of the adductor pollicis.

*Relations.* By its superficial surface with the tendons of the flexor
longus and flexor brevis digitorum, and the lumbricales. By its deep
surface with the interossei, and heads of the metatarsal bones.

**Fourth Layer.**

**Interossei Plantares.**

The **Plantar interossei** muscles are three in number, and are
placed upon rather than between the metatarsal bones. They arise
from the base of the metatarsal bones of the three outer toes, and are
inserted into the inner side of the extensor tendon and base of the first
phalanx of the same toes. In their action they are all adductors.

*Relations.* By their superficial surface with the dorsal interossei
and the metatarsal bones. By their deep surface with the external
plantar artery and veins, the adductor pollicis, transversus pedis, and
flexor minimi digiti.

*Actions.* All the preceding muscles act upon the toes; and the
movements which they are capable of executing may be referred to
four heads, viz. flexion, extension, adduction, and abduction. In these
actions they are grouped in the following manner:

<table>
<thead>
<tr>
<th>Flexion</th>
<th>Extension</th>
</tr>
</thead>
<tbody>
<tr>
<td>Flexor longus digitorum</td>

</tbody>
</table>
The great toe, like the thumb in the hand, enjoys an independent action, and is provided with distinct muscles to perform its movements. These movements are precisely the same as those of the other toes, viz.:

*Flexion.*

- Flexor longus pollicis,
- Flexor brevis pollicis.

*Extension.*

- Extensor proprius pollicis,
- Extensor brevis digitorum.

*Adduction.*

- Adductor pollicis.

*Abduction.*

- Abductor pollicis.

The only muscles excluded from this table are the lumbricales, four small muscles, which, from their attachments to the tendons of the long flexor, appear to be assistants to its action; and the transversus pedis, a small muscle placed transversely in the foot across the heads of the metatarsal bones, which has for its office the drawing together of the toes.
CHAPTER IV.

ON THE FASCIÆ.

FASCIÆ (fascia, a bandage) is the name assigned to laminae of various extent and thickness, which are distributed through the different regions of the body, for the purpose of investing or protecting the softer and more delicate organs. From a consideration of their structure, these fasciæ may be arranged into two groups: cellulo-fibrous fascia, and aponeurotic fascia.

The cellulo-fibrous fascia is best illustrated in the common subcutaneous investment of the entire body, the superficial fascia. This structure is situated immediately beneath the integument over every part of the frame, and is the medium of connection between that layer and the deeper parts. It is composed of cellulo-fibrous tissue containing in its areolæ an abundance of adipose cells. The fat being a bad conductor of caloric, serves to retain the warmth of the body; while it forms at the same time a yielding tissue, through which the minute vessels and nerves pass to the papillary layer of the skin, without incurring the risk of obstruction from injury or pressure upon the surface. By dissection, the superficial fascia may be separated into two layers, between which are found the superficial or cutaneous vessels and nerves; as the superficial epigastric artery, the saphenous veins, the radial and ulnar veins, the superficial lymphatic vessels, also the cutaneous muscles, as the platysma myoides, orbicularis palpebrarum, sphincter ani, &c. In other situations, the cellulo-fibrous fascia is found condensed into a strong and inelastic membrane, as is exemplified in the deep fascia of the neck, the thoracic, transversalis, and perineal fasciæ, and the sheaths of vessels.

The aponeurotic fascia is the strongest kind of investing membrane; it is composed of tendinous fibres, running parallel with each other, and connected by other fibres of the same kind passing in different directions. When freshly exposed, it is brilliant and nacreous, and is tough, inelastic, and unyielding. In the limbs it forms the deep fascia, enclosing and forming distinct sheaths to all the muscles and tendons. It is thick upon the outer and least protected side of the limb, and thinner upon its inner side. It is firmly connected to the bones, and to the prominent points of each region, as to the pelvis, knee, and ankle, in the lower, and to the clavicle, scapula, elbow, and wrist, in the upper extremity. It assists the muscles in their action, by keeping up a tonic pressure on their surface; aids materially in the circula-
tion of the fluids in opposition to the laws of gravity; and in the palm of the hand and sole of the foot is a powerful protection to the structures which enter into the composition of these regions. In some situations its tension is regulated by muscular action, as by the tensor vaginae femoris and gluteus maximus in the thigh, by the biceps in the leg, and by the biceps and palmaris longus in the arm; in other situations it affords an extensive surface for the origin of the fibres of muscles.

The fasciae may be arranged like the other textures of the body into, 1. Those of the head and neck. 2. Those of the trunk. 3. Those of the upper extremity. 4. Those of the lower extremity.

**FASCLE OF THE HEAD AND NECK.**

The **Temporal fascia** is a strong aponeurotic membrane which covers in the temporal muscle at each side of the head, and gives origin by its internal surface to some of its muscular fibres. It is attached to the whole extent of the temporal ridge above, and to the zygomatic arch below; in the latter situation it is thick and divided into two layers, the external being connected to the upper border of the arch, and the internal to its inner surface. A small quantity of fat is usually found between these two layers, together with the orbital branch of the temporal artery.

**Cervical fascia.**—The fasciae of the neck are the superficial and the deep. The **superficial cervical fascia** is a part of the common superficial fascia of the entire body, and is only interesting from containing between its layers the platysma myoides muscle.

The **deep cervical fascia** is a strong cellulo-fibrous layer which invests the muscles of the neck, and retains and supports the vessels and nerves. It commences posteriorly at the ligamentum nuchæ, and passes forwards at each side beneath the trapezium muscle to the posterior border of the sterno-mastoid; here it divides into two layers, which embrace that muscle and unite upon its anterior border to be prolonged onwards to the middle line of the neck, where it becomes continuous with the fascia of the opposite side. Besides thus constituting a sheath for the sterno-mastoid, it also forms sheaths for the other muscles of the neck over which it passes. If the superficial layer of the sheath of the sterno-mastoid be traced upwards, it will be found to pass over the parotid gland and masseter muscle, and to be inserted into the zygomatic arch; and if it be traced downwards, it will be seen to pass in front of the clavicle, and become lost upon the pectoralis major muscle. If the deep layer of the sheath be examined superiorly, it will be found attached to the styloid process, from which it is reflected to the angle of the lower jaw, forming the stylo-maxillary ligament; and if it be followed downwards, it will be found connected with the tendon
of the omohyoid muscle, and may thence be traced behind the clavicle, where it encloses the subclavius muscle, and, being extended from the cartilage of the first rib to the coracoid process, constitutes the costocoracoid membrane. In front of the sternomastoid muscle, the deep

fascia is attached to the border of the lower jaw and os hyoides, and forms a distinct sheath for the submaxillary gland. Inferiorly it divides into two layers, one of which passes in front of the sternum, while the other is attached to its superior border.

* A transverse section of the neck, shewing the deep cervical fascia and its numerous prolongations, forming sheaths for the different muscles. As the figure is symmetrical, the figures of reference are placed only on one side. 1. The platysma myoides. 2. The trapezius. 3. The ligamentum nuchae, from which the fascia may be traced forwards beneath the trapezius, enclosing the other muscles of the neck. 4. The point at which the fascia divides, to form a sheath for the sternomastoid muscle (5). 6. The point of reunion of the two layers of the sternomastoid sheath. 7. The point of union of the deep cervical fascia of opposite sides of the neck. 8. Section of the sternohyoid. 9. Omo-hyoid. 10. Sterno-thyroid. 11. The lateral lobe of the thyroid gland. 12. The trachea. 13. The oesophagus. 14. The sheath containing the common carotid artery, internal jugular vein, and pneumogastric nerve. 15. The longus colli. The nerve in front of the sheath of this muscle is the sympathetic. 16. The rectus anticus major. 17. Scalenus anticus. 18. Scalenus posticus. 19. The splenius capitis. 20. Splenius colli. 21. Levator anguli scapulae. 22. Complexus. 23. Tracheo-mastoid. 24. Transversalis colli. 25. Cervicalis ascendens. 26. The semi-spinalis colli. 27. The multifidus spinæ. 28. A cervical vertebra. The transverse processes are seen to be traversed by the vertebral artery and vein.
FASCÉ OF THE TRUNK.

The *thoracic fascia* is a dense layer of cellulo-fibrous membrane stretched horizontally across the superior opening of the thorax. It is firmly attached to the concave margin of the first rib, and to the inner surface of the sternum. In front it leaves an opening for the connection of the cervical with the thoracic portion of the thymus gland, and behind it forms an arch across the vertebral column, to give passage to the esophagus.

At the point where the great vessels and trachea pass through the thoracic fascia, it divides into an ascending and descending layer. The *ascending layer* is attached to the trachea, and becomes continuous with the sheath of the carotid vessels, and with the deep cervical fascia; the *descending layer* descends upon the trachea to its bifurcation, surrounds the large vessels arising from the arch of the aorta, and the upper part of the arch itself, and is continuous with the fibrous layer of the pericardium. It is connected also with the vena innominatae and superior cava, and is attached to the cellular capsule of the thymus gland.

"The thoracic fascia," writes Sir Astley Cooper, "performs three important offices:—

"1st. It forms the upper boundary of the chest, as the diaphragm does the lower.

"2nd. It steadily preserves the relative situation of the parts which enter and quit the thoracic opening.

"3rd. It attaches and supports the heart in its situation, through the medium of its connection with the aorta and large vessels which are placed at its curvature."

ABDOMINAL FASCÉ.

The lower part of the parietes of the abdomen, and the cavity of the pelvis, are strengthened by a layer of fascia which lines their internal surface, and at the bottom of the latter cavity is reflected inwards to the sides of the bladder. This fascia is continuous throughout the whole of the above-mentioned surface; but for convenience of description is considered under the several names of transversalis fascia, iliac fascia, and pelvic fascia; the two former meet at the crest of the ilium and Poupart's ligament, and the latter is confined to the cavity of the true pelvis.

The *fascia transversalis* (Fascia Cooperi) is a cellulo-fibrous lamella which lines the inner surface of the transversalis muscle. It is thick and dense below, near the lower part of the abdomen; but becomes thinner as it ascends, and is gradually lost in the subserous cellular

* For an excellent description of this fascia, see Sir Astley Cooper's work on the "Anatomy of the Thymus Gland."

† Sir Astley Cooper first described this fascia in its important relation to inguinal hernia.
tissue. It is attached inferiorly to the reflected margin of Poupart's ligament and to the crest of the ilium; internally, to the border of the rectus muscle; and, at the inner third of the femoral arch, is continued beneath Poupart's ligament, and forms the anterior segment of the crural canal, or sheath of the femoral vessels.

The internal abdominal ring is situated in this fascia, at about midway between the spine of the os pubis and the anterior superior spine of the ilium, and half an inch above Poupart's ligament; it is bounded upon its inner side by a well-marked falciform border, but is ill defined around its outer margin. From the circumference of this ring is given off an infundibiliform process, which surrounds the testicle and spermatic cord, constituting the fascia propria of the latter, and forms the first investment to the sac of oblique inguinal hernia. It is the strength of this fascia, in the interval between the tendon of the rectus and the internal abdominal ring, that defends this portion of the parietes from the frequent occurrence of direct inguinal hernia.

INGUINAL HERNIA.

Inguinal hernia is of two kinds, oblique and direct.

In Oblique inguinal hernia the intestine escapes from the cavity of the abdomen into the spermatic canal, through the internal abdominal ring, pressing before it a pouch of peritoneum which constitutes the hernial sac, and distending the infundibiliform process of the transversalis fascia. After emerging through the internal abdominal ring, it passes first beneath the lower and arched border of the transversalis muscle; then beneath the lower border of the internal oblique muscle; and finally through the external abdominal ring in the aponeurosis of the external oblique. From the transversalis muscle it receives no investment; while passing beneath the lower border of the internal oblique it obtains the cremaster muscle; and, upon escaping at the external abdominal ring, receives the intercolumnar fascia. So that the coverings of an oblique inguinal hernia, after it has emerged through the external abdominal ring, are, from the surface to the intestine, the

Integument,
Superficial fascia,
Intercolumnar fascia,
Cremaster muscle,
Transversalis, or infundibiliform fascia,
Peritoneal sac.

The spermatic canal, which, in the normal condition of the abdominal parietes serves for the passage of the spermatic cord in the male, and the round ligament with its vessels in the female, is about one inch and a half in length. It is bounded in front by the aponeurosis of the external oblique muscle; behind by the transversalis fascia, and the conjoined tendon of the internal oblique and transversalis muscle; above by the arched borders of the internal oblique and transversalis;
by the grooved border of Poupart's ligament; and at each extremity by one of the abdominal rings, the internal ring at the inner termination, the external ring at the outer extremity. These relations may be more distinctly illustrated by the following plan—

_Above._

_Lower borders of internal oblique and transversalis muscle._

_Below._

Grooved border of Poupart's ligament.

There are three varieties of oblique inguinal hernia:—common, congenital, and encysted.

_Common oblique hernia_ is that which has been described above.

_Congenital hernia_ results from the nonclosure of the pouch of peritoneum carried downwards into the scrotum by the testicle, during its descent in the foetus.

The intestine at some period of life is forced into this canal, and descends through it into the tunica vaginalis where it lies in contact with the testicle; so that congenital hernia has no proper sac, but is contained within the tunica vaginalis. The other coverings are the same as those of common inguinal hernia.

_Encysted hernia_ (hernia infantilis, of Hey) is that form of protrusion in which the pouch of peritoneum forming the tunica vaginalis, being only partially closed, and remaining open externally to the abdomen, admits of the hernia passing into the scrotum, behind the tunica vaginalis. So that the surgeon in operating upon this variety, requires to divide three layers of serous membrane; the first and second layers being those of the tunica vaginalis; and the third the true sac of the hernia.

DIRECT INGUINAL HERNIA has received its name from passing _directly_ through the external abdominal ring, and forcing before it the opposing parietes. This portion of the wall of the abdomen is strengthened by the conjoined tendon of the internal oblique and transversalis muscle, which is pressed before the hernia, and forms one of its investments. Its coverings are, the

_integument, superficial fascia, intercolunnar fascia, conjoined tendon, transversalis fascia, peritoneal sac._
Direct inguinal hernia differs from oblique in never attaining the
same bulk, in consequence of the resisting nature of the conjoined
tendon of the internal oblique and transversalis and of the transversalis
fascia; in its direction, having a tendency to protrude from the
middle line rather than towards it. Thirdly, in making for itself a
new passage through the abdominal parietes, instead of following a
natural channel; and fourthly, in the relation of the neck of its sac
to the epigastric artery; that vessel lying to the outer side of the
opening of the sac of direct hernia, and to the inner side of that of
oblique hernia.

All the forms of inguinal hernia are designated scrotal, when they
have descended into that cavity.

The Fascia iliaca is the aponeurotic investment of the psoas and
iliacus muscles; and, like the fascia transversalis, is thick below, and
becomes gradually thinner as it ascends. It is attached superiorly along
the edge of the psoas, to the anterior lamella of the aponeurosis of the
transversalis muscle, to the ligamentum arcuatum internum, and to the
bodies of the lumbar vertebrae, leaving arches corresponding with the
constricted portions of the vertebrae for the passage of the lumbar
vessels. Lower down it passes beneath the external iliac vessels, and
is attached along the margin of the true pelvis; externally, it is con-
ected to the crest of the ilium; and, inferiorly, to the outer two-thirds
of Poupart's ligament, where it is continuous with the fascia trans-
versalis. Passing beneath Poupart's ligament, it surrounds the psoas
and iliacus muscles to their termination, and beneath the inner third
of the femoral arch forms the posterior segment of the sheath of the
femoral vessels.

The Fascia pelvica is attached to the inner surface of the os pubis
and along the margin of the brim of the pelvis, where it is continuous
with the iliac fascia. From this extensive origin it descends into the
pelvis, and divides into two layers, the pelvic and obturator.

The pelvic layer or fascia, when traced from the internal surface of
the os pubis near the symphysis, is seen to be reflected inwards to the
neck of the bladder, so as to form the anterior vesical ligaments.
Traced backwards, it passes between the sacral plexus of nerves and
the internal iliac vessels, and is attached to the anterior surface of the
sacrum; and followed from the sides of the pelvis, it descends to the
base of the bladder and divides into three layers, one ascending, is re-
lected upon the side of that viscus, encloses the vesical plexus of veins,
and forms the lateral ligaments of the bladder. A middle layer passes
inwards between the base of the bladder and the upper surface of the
rectum, and was named by Mr. Tyrrell the recto-vesical fascia; and an
inferior layer passes behind the rectum, and, with the layer of the
opposite side, completely invests that intestine.

The obturator fascia passes directly downwards from the splitting
of the layers of the pelvic fascia, and covers in the obturator internus
muscle and the internal pudic vessels and nerve; it is attached to the
ramus of the os pubis and ischium in front, and below to the falciform
PERINEAL FASCIA.

Fig. 112.*

margin of the great sacro-ischiatic ligament. Lying between these two layers of fascia is the levator ani muscle, which arises from their angle of separation. The levator ani is covered in inferiorly by a third layer of fascia, which is given off by the obturator fascia, and is continued downwards upon the inferior surface of the muscle to the extremity of the rectum, where it is lost. This layer may be named from its position and inferior attachment the anal fascia.

PERINEAL FASCIA.—In the perineum there are two fasciae of much importance, the superficial and deep perineal fascia.

The superficial perineal fascia is a thin aponeurotic layer, which covers in the muscles of the genital portion of the perineum and the root of the penis. It is firmly attached at each side to the ramus of the os pubis and ischium; posteriorly it is reflected backwards beneath the transversi perinei muscles to become connected with the deep perineal fascia; while anteriorly it is continuous with the dartos of the scrotum.

The deep perineal fascia (Camper’s ligament, triangular ligament)

* A transverse section of the pelvis, shewing the distribution of the pelvic fascia. 1. The bladder. 2. The vesicula seminalis of one side divided across. 3. The rectum. 4. The iliac fascia covering in the iliacus and psoas muscles (5); and forming a sheath for the external iliac vessels (6). 7. The anterior crural nerve excluded from the sheath. 8. The pelvic fascia. 9. Its ascending layer, forming the lateral ligament of the bladder of one side, and a sheath to the vesical plexus of veins. 10. The recto-vesical fascia of Mr. Tyrrell formed by the middle layer. 11. The inferior layer surrounding the rectum and meeting at the middle line with the fascia of the opposite side. 12. The levator ani muscle. 13. The obturator internus muscle, covered in by the obturator fascia, which also forms a sheath for the internal pudic vessels and nerve (14). 15. The layer of fascia which invests the under surface of the levator ani muscle, the anal fascia.
is situated behind the root of the penis, and is firmly stretched across between the ramus of the os pubis and ischium of each side, so as to constitute a strong septum of defence to the outlet of the pelvis. At its inferior border it divides into two layers, one of which is continued forwards, and is continuous with the superficial perineal fascia; while the other is prolonged backwards to the rectum, and, joining with the anal fascia, assists in supporting the extremity of that intestine. The deep perineal fascia is composed of two layers, which are separated from each other by several important parts, and traversed by the membranous portion of the urethra. The anterior layer is nearly plane in its direction, and sends a sheath forwards around the anterior termination of the membranous urethra to be attached to the posterior part of the bulb. The posterior layer is oblique and sends a funnel-shaped process backwards, which invests the commencement of the membranous urethra and the prostate gland. The inferior segment of this funnel-shaped process is continued backward beneath the prostate

The membranous portion, enclosed by the compressor urethrae muscle. 11. The commencement of the corpus spongiosum penis, the bulb. 12. The anterior ligaments of the bladder formed by the reflection of the pelvic fascia, from the internal surface of the os pubis to the neck of the bladder. 13. The edge of the pelvic fascia at the point where it is reflected upon the rectum. 14. An interval between the pelvic fascia and deep perineal fascia, occupied by a plexus of veins. 15. The deep perineal fascia; its two layers. 16. Cowper's gland of the right side situated between the two layers below the membranous portion of the urethra. 17. The superficial perineal fascia ascending in front of the root of the penis to become continuous with the dartos of the scrotum (18). 19. The layer of the deep fascia which is prolonged to the rectum. 20. The lower part of the levator ani; its fibres are concealed by the anal fascia. 21. The inferior segment of the funnel-shaped process given off from the posterior layer of the deep perineal fascia, which is continuous with the recto-vesical fascia of Tyrrell. The attachment of this fascia to the recto-vesical fold of peritoneum is seen at 22.
the compressor urethrae muscle, Cowper's glands, the internal pudic and bulbous arteries, and a plexus of veins. Mr. Tyrrell considers the anterior lamella alone as the deep perineal fascia, and the posterior lamella as a distinct layer of fascia covering in a considerable plexus of veins.

**FASCIAE OF THE UPPER EXTREMITY.**

The superficial fascia of the upper extremity contains between its layers the superficial veins and lymphatics, and the superficial nerves.

The deep fascia is thin over the deltoid and pectoralis major muscles, and in the axillary space, but thick upon the dorsum of the scapula, where it binds down the infra-spinatus muscle. It is attached to the clavicle, acromion process, and spine of the scapula. In the upper arm it is somewhat stronger, and is inserted into the condyloid ridges, forming the intermuscular septa. In the fore-arm it is very strong, and at the bend of the elbow its thickness is augmented by a broad band, which is given off from the inner side of the tendon of the biceps. It is firmly attached to the olecranon process, to the ulna, and to the prominent points about the wrist. Upon the front of the wrist it is continuous with the anterior annular ligament, which is considered by some anatomists to be formed by the deep fascia, but which I am more disposed to regard as a ligament of the wrist. On the posterior aspect of this joint it forms a strong transverse band, the posterior annular ligament, beneath which the tendons of the extensor muscles pass, in distinct sheaths. The attachments of the posterior annular ligament are, the radius on one side, and the ulna and pisiform bone on the opposite side of the joint.

The tendons, as they pass beneath the annular ligaments, are surrounded by synovial bursae. The dorsum of the hand is invested by a thin fascia, which is continuous with the posterior annular ligament.

The palmar fascia is divided into three portions. A central portion, which occupies the middle of the palm, and two lateral portions, which spread out over the sides of the hand, and are continuous with the dorsal fascia. The central portion is strong and tendinous: it is narrow at the wrist, where it is attached to the annular ligament, and broad over the heads of the metacarpal bones, where it divides into eight slips, which are inserted into the sides of the base of the first phalanx of each finger. The fascia is strengthened at its point of division into slips by strong fasciculi of transverse fibres, and the arched interval left between the slips gives passage to the tendons of the flexor muscles. The arches between the fingers transmit the digital vessels and nerves, and lumbricales muscles.
The *superficial fascia* contains between its two layers the superficial vessels and nerves of the lower extremity. At the groin these two layers are separated from each other by the superficial lymphatic glands, and the deep layer is attached to Poupart's ligament, while the superficial layer is continuous with the superficial fascia of the abdomen.

The *deep fascia* of the thigh is named, from its great extent, the *fascia lata*; it is thick and strong upon the outer side of the limb, and thinner upon its inner and posterior side. That portion of fascia which invests the gluteus maximus is very thin, but that which covers in the gluteus medius is excessively thick, and gives origin, by its inner surface, to the superficial fibres of that muscle. The *fascia lata* is attached superiorly to Poupart's ligament, the crest of the ilium, sacrum, coccyx, tuberosity of the ischium, ramus of the ischium and pubes, and body of the pubes; in the thigh it is inserted into the linea aspera, and around the knee is connected with the prominent points of that joint. It possesses also two muscular attachments, by means of the tensor vaginae femoris, which is inserted between its two layers on the outer side, and the gluteus maximus, which is attached to it behind.

In addition to the smaller openings in the *fascia lata* which transmit the small cutaneous vessels and nerves, there exists at the upper and inner extremity of the thigh an oblique foramen, which gives passage to the superficial lymphatic vessels, and the large subcutaneous vein of the lower extremity, the internal saphenous vein, and is thence named the *saphenous opening*. The existence of this opening has given rise to the division of the upper part of the *fascia lata* into two portions, an iliac portion and a pubic portion.

The *iliac portion* is situated upon the iliac side of the opening. It is attached to the crest of the ilium, and along Poupart's ligament to the spine of the os pubis, whence it is reflected downwards and outwards in an arched direction, and forms a falciform border, which constitutes the outer boundary of the saphenous opening. The edge of this border immediately overlies, and is reflected upon, the sheath of the femoral vessels, and the lower extremity of the curve is continuous with the pubic portion.

The *pubic portion*, occupying the pubic side of the saphenous opening, is attached to the spine of the os pubis and pectineal line; and, passing outwards behind the sheath of the femoral vessels, divides into two layers; the anterior layer is continuous with that portion of the iliac fascia which forms the sheath of the iliacus and psoas muscles, and the posterior layer is lost upon the capsule of the hip-joint.

The interval between the falciform border of the iliac portion and the opposite surface of the pubic portion is closed by a fibrous layer, which is pierced by numerous openings for the passage of lymphatic
vessels, and is thence named *cribriform fascia*. The cribriform fascia is connected with the sheath of the femoral vessels, and forms one of the coverings of femoral hernia. When the iliac portion of the fascia lata is removed from its attachment to Poupart's ligament and is turned aside, the sheath of the femoral vessels (the *femoral or crural canal*) is brought into view; and if Poupart's ligament be carefully divided, the sheath may be isolated, and its continuation with the transversalis and iliac fascia clearly demonstrated. In this view the sheath of the femoral vessels is an infundibiliform continuation of the abdominal fasciae, closely adherent to the vessels a little way down the thigh, but much larger than the vessels it contains at Poupart's ligament. If the sheath be opened, the artery and vein will be found lying side by side, and occupying the outer two-thirds of the sheath, leaving an infundibiliform interval between the vein and the inner

---

* A section of the structures which pass beneath the femoral arch. 1. Poupart's ligament. 2. 2. The iliac portion of the fascia lata, attached along the margin of the crest of the ilium, and along Poupart's ligament, as far as the spine of the os pubis (3). 4. The pubic portion of the fascia lata, continuous at 3 with the iliac portion, and passing outwards behind the sheath of the femoral vessels to its outer border at 5, where it divides into two layers; one is continuous with the sheath of the psoas (6) and iliacus (7); the other (8) is lost upon the capsule of the hip-joint (9). 10. The crural nerve, enclosed in the sheath of the psoas and iliacus. 11. Gimbernat's ligament. 12. The femoral ring, within the femoral sheath. 13. The femoral vein. 14. The femoral artery; the two vessels and the ring are surrounded by the femoral sheath, and thin septa are sent between the anterior and posterior wall of the sheath, dividing the artery from the vein, and the vein from the femoral ring.
wall of the sheath. The superior opening of this space is named the femoral ring; it is bounded in front by Poupart’s ligament, behind by the os pubis, internally by Gimbernat’s ligament, and externally by the femoral vein. The interval itself serves for the passage of the superficial lymphatic vessels from the saphenous opening to a lymphatic gland, which generally occupies the femoral ring; and from thence they proceed into the current of the deep lymphatics. The femoral ring is closed merely by a thin layer of subserous areolar tissue,* which retains the lymphatic gland in its position and is named septum crurale; and by the peritoneum. It follows from this description, that the femoral ring must be a weak point in the parietes of the abdomen, particularly in the female, where the femoral arch, or space included between Poupart’s ligament and the border of the pelvis, is larger than in the male, while the structures which pass through it are smaller. It happens consequently, that, if violent or continued pressure be made upon the abdominal viscera, a portion of intestine may be forced through the femoral ring into the infundibuliform space in the sheath of the femoral vessels, carrying before it the peritoneum and the septum crurale,—this constitutes femoral hernia. If the causes which give rise to the formation of this hernia continue, the intestine, unable to extend further down the sheath, from the close connection of the latter with the vessels, will in the next place be forced forwards through the saphenous opening in the fascia lata, carrying before it two additional coverings, the sheath of the vessels, or fascia propria, and the cribriform fascia; and then curving upwards over Poupart’s ligament, the hernia will become placed beneath the superficial fascia and integument.

The direction which femoral hernia takes in its descent is at first downwards, then forwards, and then upwards; and in endeavouring to reduce it, the application of the taxis must have reference to this course, and be directed in precisely the reverse order. The coverings of femoral hernia are the

The Fascia of the leg is strong in the anterior tibial region, and gives origin by its inner surface to the upper part of the tibialis anticus, and extensor longus digitorum muscles.

It is firmly attached to the tibia and fibula at each side, and becomes thickened inferiorly into a narrow band, the anterior annular

* This areolar tissue is sometimes very considerably thickened by a deposit of fat within its areolae, and forms a thick stratum over the hernial sac.
ligament, beneath which the tendons of the extensor muscles pass into the dorsum of the foot, in distinct sheaths lined by synovial bursae. Upon the outer side it forms a distinct sheath which envelopes the peronei muscles, and ties them to the fibula. The anterior annular ligament is attached by one extremity to the outer side of the os calcis, and divides in front of the joint into two bands; one of which is inserted into the inner malleolus, while the other spreads over the inner side of the foot, and becomes continuous with the internal portion of the plantar fascia.

The fascia of the dorsum of the foot is a thin layer given off from the lower border of the anterior annular ligament; it is continuous at each side with the lateral portions of the plantar fascia.

The fascia of the posterior part of the leg is much thinner than the anterior, and consists of two layers, superficial and deep. The superficial layer is continuous with the posterior fascia of the thigh, and is increased in thickness upon the outer side of the leg by an expansion derived from the tendon of the biceps; it terminates inferiorly in the external and internal annular ligaments. The deep layer is stretched across between the tibia and fibula, and forms the intermuscular fascia between the superficial and deep layer of muscles. It covers in superiorly the popliteus muscle, receiving a tendinous expansion from the semi-membranosus muscle, and is attached to the oblique line of the tibia.

The internal annular ligament is a strong fibrous band attached above to the internal malleolus, and below to the side of the inner tuberosity of the os calcis. It is continuous above with the posterior fascia of the leg, and below with the plantar fascia, forming sheaths for the passage of the flexor tendons and vessels, into the sole of the foot.

The external annular ligament, shorter than the internal, extends from the extremity of the outer malleolus to the side of the os calcis, and serves to bind down the tendons of the peronei muscles in their passage beneath the external ankle.

The Plantar Fascia consists of three portions, a middle and two lateral.

The middle portion is thick and dense, and is composed of strong aponeurotic fibres, closely interwoven with each other. It is attached posteriorly to the inner tuberosity of the os calcis, and terminates under the heads of the metatarsal bones in five fasciculi. Each of these fasciculi divides into two slips, which are inserted one on each side into the bases of the first phalanges of the toes, leaving an interval between them for the passage of the flexor tendons. The point of division of this fascia into fasciculi and slips, is strengthened by transverse bands, which preserve the solidity of the fascia at its broadest part. The intervals between the toes give passage to the digital arteries and nerves and the lumbricales muscles.

The lateral portions are thin, and cover the sides of the sole of the foot; they are continuous behind with the internal and external an-
PLANTAR FASCIA.

nular ligaments; on the inner side with the middle portion, and externally with the dorsal fascia.

Besides constituting a strong layer of investment and defence to the soft parts situated in the sole of the foot, these three portions of fascia send processes inwards, which form sheaths for the different muscles. A strong septum is given off from each side of the middle portion of the plantar fascia, which is attached to the tarsal bones, and divides the muscles into three groups, a middle and two lateral; and transverse septa are stretched between these to separate the layers. The superficial layer of muscles derive a part of their origin from the plantar fascia.
CHAPTER V.

ON THE ARTERIES.

The arteries are the cylindrical tubes which convey the blood from the ventricles of the heart to every part of the body. They are dense in structure, and preserve for the most part the cylindrical form when emptied of their blood, which is their condition after death: hence they were considered by the ancients as the vessels for the transmission of the vital spirits, and were therefore named arteries (ἀνεσίν, to contain air).

The artery proceeding from the left ventricle of the heart contains the pure or arterial blood, which is distributed throughout the entire system, and constitutes with its returning veins the greater or systemic circulation. That which emanates from the right ventricle, conveys the impure blood to the lungs; and with its corresponding veins establishes the lesser or pulmonary circulation.

The whole of the arteries of the systemic circulation proceed from a single trunk, named the aorta, from which they are given off as branches, and divide and subdivide to their ultimate ramifications, constituting the great arterial tree which pervades by its minute subdivisions every part of the animal frame. The mode in which the division into branches takes place is deserving of remark. From the aorta the branches, for the most part, pass off at right angles, as if for the purpose of checking the impetus with which the blood would otherwise rush along their cylinders from the main trunk; but in the limbs a very different arrangement is adopted; the branches are given off from the principal artery at an acute angle, so that no impediment may be offered to the free circulation of the vital fluid. The division of arteries is usually dichotomous, as of the aorta into the two common iliacs, common carotid into the external and internal, &c.; but in some few instances a short trunk divides suddenly into several branches which proceed in different directions; this mode of division is termed an axis, as the thyroid and cælic axis.

In the division of an artery into two branches, it is observed that the combined area of the two branches are somewhat greater than that of the single trunk; and if the combined area of all the branches at the periphery of the body were compared with that of the aorta, it would be seen that the blood, in passing from the aorta into the numerous distributing branches, was flowing through a conical tube, of

* To Galen is due the honour of having discovered that arteries contained blood, and not air.
which the apex might be represented by the aorta, and the base by
the surface of the body. The advantage of this important principle in
facilitating the circulation is sufficiently obvious; for the increased
channel which is thus provided for the current of the blood, serves to
compensate for the retarding influence of friction, resulting from the
distance of the heart and the division of the vessels.

Communications between arteries are very free and numerous, and
increase in frequency with the diminution in the size of the branches;
so that through the medium of the minute ramifications, the entire
body may be considered as one uninterrupted circle of inosculations, or
anastomoses (ἀνάστομος between, στόμα mouth). This increase in the fre-
quency of anastomosis in the smaller branches is a provision for coun-
teracting the greater liability to impediment existing in them than in
the larger branches. Where freedom of circulation is of vital impor-
tance, this communication of the arteries is very remarkable, as in the
circle of Willis in the cranium, or in the distribution of the arteries of
the heart. It is also strikingly seen in situations where obstruction is
most likely to occur, as in the distribution to the alimentary canal,
around joints, or in the hand and foot. Upon this free communication
existing everywhere between arterial branches is founded the prin-
ciple of cure in the ligature of large arteries; the ramifications of the
branches given off from the artery above the ligature inosculate with
those which proceed from the trunk of the vessel below the ligature:
these anastomosing branches enlarge and constitute a collateral cir-
culation, in which, as is shewn in the beautiful preparations made by
Sir Astley Cooper, several large branches perform the office of the
single obliterated trunk.*

The arteries do not terminate directly in veins; but in an inter-
mediate system of vessels, which, from their minute size (about
\( \frac{1}{800} \) of an inch in diameter), are termed capillaries (capillus, a hair).
The capillaries constitute a microscopic network, which is distributed
through every part of the body, so as to render it impossible to intro-
duce the smallest needle point beneath the skin without wound-
ing several of these fine vessels. It is through the medium of the
capillaries, that all the phenomena of nutrition and secretion are
performed. They are remarkable for their uniformity of diameter,
and for the constant divisions and communications which take place
between them, without any alteration of size. They inosculate on
one hand with the terminal ramusculi of the arteries; and on the
other with the minute radicles of the veins.

Arteries are composed of three coats, external, middle, and internal.
The external or cellulo-fibrous coat is firm and strong, and serves at
the same time as the chief means of resistance of the vessel, and of
connection to surrounding parts. It consists of condensed fibro-cellu-
lar tissue, strengthened by an interlacement of glistening fibres which

* I have a preparation, shewing the collateral circulation in a dog, in which I
tied the abdominal aorta; the animal died from over-feeding nearly two years
after the operation.
are partly longitudinal and partly encircle the cylinder of the tube in an oblique direction. Upon the surface the cellular tissue is loose, to permit of the movements of the artery in distention and contraction.

The middle coat is that upon which the thickness of the artery depends; it is yellowish in colour, and so brittle as to be cut through by the thread in the ligature of a vessel.

The internal coat is a thin serous membrane which lines the interior of the artery, and gives it the smooth polish which that surface presents. It is continuous with the lining membrane of the heart, and through the medium of the capillaries with that of the venous system.

In intimate structure an artery is more complicated than the above description would imply. The internal coat, for example, is composed of two layers, and the middle of three, so that with the external coat there are six layers entering into the composition of an artery. The innermost coat is a tesselated epithelium analogous to that of other serous membranes. The second coat from within is a thin, rigid membrane, pierced with a number of round or oval-shaped holes, and supporting a thin layer of flat, longitudinal fibres. From these characters it has been denominated the fenestrated or striated coat. The third layer, which is the innermost part of the middle coat, is composed of flat, longitudinal fibres, analogous to those of organic muscle. The fourth layer, the thickest of the whole, is composed of muscular fibres of organic life, arranged in a circular direction around the vessel. The fifth, or outermost part of the middle coat is a thin layer of elastic tissue; this is present only in the large arteries. The sixth is the external or cellulo-fibrous coat.

The arteries in their distribution through the body are included in a loose cellular investment which separates them from the surrounding tissues, and is called a sheath. Around the principal vessels the sheath is an important structure; it is composed of cellulo-fibrous tissue, intermingled with tendinous fibres, and is continuous with the fasciae of the region in which the arteries are situated, as with the thoracic and cervical fasciae in the neck, transversalis and iliac fasciae, and fascia lata in the thigh, &c. The sheath of the arteries contains also their accompanying veins, and sometimes a nerve.

The coats of arteries are supplied with blood like other organs of the body, and the vessels which are distributed to them are named vasa vasorum. They are also provided with nerves; but the mode of distribution of the nerves is at present unknown.

In the consideration of the arteries, we shall first describe the aorta, and the branches of that trunk, with their subdivisions, which together constitute the efferent portion of the systemic circulation; and then the pulmonary artery as the efferent trunk of the pulmonary circulation.
*The large vessels which proceed from the root of the heart, with their relations; the heart has been removed. 1. The ascending aorta. 2. The arch. 3. The thoracic portion of the descending aorta. 4. The arteria innominata dividing into, 5, the right carotid, which again divides at 6, into the external and internal carotid; and 7, the right subclavian artery. 8. The axillary artery; its extent is designated by a dotted line. 9. The brachial artery. 10. The right pneumogastric nerve running by the side of the common carotid, in front of the right subclavian artery, and behind the root of the right lung. 11. The left common carotid, having to its outer side the left pneumogastric nerve, which crosses the arch of the aorta, and as it reaches its lower border is seen to give off the left recurrent nerve. 12. The left subclavian artery becoming axillary, and brachial in its course, like the artery of the opposite side. 13. The trunk of the pulmonary artery connected to the concavity of the arch of the aorta by a fibrous cord, the remains of the ductus arteriosus. 14. The left pulmonary artery. 15. The right pulmonary artery. 16. The trachea. 17. The right bronchus. 18. The left bronchus. 19, 19. The pulmonary veins. 17, 15, and 19, on the right side, and 14, 18, and 19, on the left, constitute the roots of the corresponding lungs, and the relative position of these vessels is preserved. 20. Bronchial arteries. 21, 21. Intercostal arteries; the branches from the front of the aorta above and below the number 3 are pericardiac and cesophageal branches.
AORTA.

The aorta arises from the left ventricle, at the middle of the root of the heart, and opposite the articulation of the fourth costal cartilage with the sternum. At its commencement it presents three dilatations, called the sinus aortici, which correspond with the three semilunar valves. It ascends at first to the right, then curves backwards and to the left, and descends on the left side of the vertebral column to the fourth lumbar vertebra. Hence it is divided into — ascending — arch—and descending aorta.

Relations.—The ascending aorta has in relation with it, in front, the trunk of the pulmonary artery, thoracic fascia, and pericardium; behind, the right pulmonary veins and artery; to the right side, the right auricle and superior cava; and to the left, the left auricle and the trunk of the pulmonary artery.

Arch.—The upper border of the arch of the aorta is parallel with the upper border of the second sterno-costal articulation of the right side in front, and the second dorsal vertebra behind, and terminates opposite the lower border of the third.

The anterior surface of the arch is crossed by the left pneumogastric nerve, and by the cardiac branches of that nerve and of the sympathetic. The posterior surface of the arch is in relation with the bifurcation of the trachea and great cardiac plexus, the cardiac nerves, left recurrent nerve, and the thoracic duct. The superior border gives off the three great arteries, viz. the innominata, left carotid, and left subclavian. The inferior border, or concavity of the arch, is in relation with the remains of the ductus arteriosus, the cardiac ganglion and left recurrent nerve, and has passing beneath it the right pulmonary artery and left bronchus.
ARCH OF THE AORTA.—THORACIC AORTA.

The descending aorta is subdivided in correspondence with the two great cavities of the trunk, into the thoracic and abdominal aorta. The Thoracic aorta is situated to the left side of the vertebral column, but approaches the middle line as it descends, and at the aortic opening of the diaphragm is altogether in front of the column. After entering the abdomen it again falls back to the left side.

_Relations._—It is in relation, _behind_ with the vertebral column and lesser vena azygos; _in front_ with the œsophagus and right pneumogastric nerve; to the _left side_ with the pleura; and to the _right_ with the thoracic duct.

_Behind._
Lesser vena azygos,
Vertebral column.

The Abdominal aorta enters the abdomen through the aortic opening of the diaphragm, and descends, lying rather to the left side of the vertebral column, to the fourth lumbar vertebra, where it divides into the two common iliac arteries.

_Relations._—It is crossed, _in front_ by the left renal vein, pancreas, transverse duodenum, and mesentery, and is embraced by the aortic plexus; _behind_ it is in relation with the thoracic duct, receptaculum chyli, and left lumbar veins.
On its left side is the left semilunar ganglion and sympathetic nerve; and on the right the vena cava, right semilunar ganglion, and the commencement of the vena azygos.

Plan of the Relations of the Abdominal Aorta.

**In Front.**

**Left Side.**
- Left semilunar ganglion,
- Sympathetic nerve.

**Behind.**
- Thoracic duct,
- Receptaculum chyli,
- Left lumbar veins.

**Branches.** The branches of the aorta, arranged in a tabular form, are,—

**Ascending aorta**
- Coronary.

**Arch of the aorta**
- Arteria innominata
  - Right carotid,
  - Left carotid,
  - Left subclavian.
- Pericardiac,
- Bronchial,
- Oesophageal,
- Intercostal.

**Thoracic aorta**
- Phrenic,
- Cœliac axis,
  - Gastric,
  - Hepatic,
  - Splenic.
- Supra-renal,
- Renal,
- Superior mesenteric,
- Spermatic,
- Inferior mesenteric,
- Lumbar,
- Sacra media,
- Common iliacs.

The **Coronary arteries** arise from the aortic sinuses at the commencement of the ascending aorta, immediately above the free margin of the semilunar valves. The left, or anterior coronary, passes forwards, between the pulmonary artery and left appendix auriculæ, and
divides into two branches; one of which winds around the base of the left ventricle in the auriculo-ventricular groove, and inosculates with the right coronary, forming an arterial circle around the base of the heart; while the other passes along the line of union of the two ventricles, upon the anterior aspect of the heart, to its apex, where it anastomoses with the descending branch of the right coronary. It supplies the left auricle and the adjoining sides of both ventricles.

The right, or posterior coronary, passes forwards, between the root of the pulmonary artery and the right auricle, and winds along the auriculo-ventricular groove, to the posterior median furrow, where it descends upon the posterior aspect of the heart to its apex, and inosculates with the left coronary. It is distributed to the right auricle, and to the posterior surface of both ventricles, and sends a large branch along the sharp margin of the right ventricle to the apex of the heart.

ARTERIA INNOMINATA.

The Arteria innominata (fig. 116, No. 4) is the first artery given off by the arch of the aorta. It is an inch and a half in length, and ascends obliquely towards the right sterno-clavicular articulation, where it divides into the right carotid and right subclavian artery.

Relations.—It is in relation, in front with the left vena innominata, the thymus gland, and the origins of the sterno-thyroid and sterno-hyoid muscles, which separate it from the sternum. Behind with the trachea, pneumogastric nerve and cardiac nerves; externally with the right vena innominata and pleura; and internally with the origin of the left carotid.

Plan of the Relations of the Arteria Innominata.

In Front.

Left vena innominata, Thymus gland, Stermo-thyroid, Stermo-hyoid.

Right Side.

Right vena innominata, Pleura.  

Arteria innominata.  

Left Side.

Left carotid.

Behind.

Trachea, Pneumogastric nerve, Cardiac nerves.

The arteria innominata occasionally gives off a small branch, which ascends along the middle of the trachea to the thyroid gland. This branch was described by Neubauer, and Dr. Harrison names it the middle thyroid artery. A knowledge of its existence is important in performing the operation of tracheotomy.
COMMON CAROTID ARTERIES.

The common carotid arteries (ząga, the head,) arise, the right from the bifurcation of the arteria innominata opposite the right sterno-clavicular articulation, the left from the arch of the aorta. It follows, therefore, that the right carotid is shorter than the left; it is also more anterior; and, in consequence of proceeding from a branch instead of from the main trunk, it is larger than its fellow.

The Right common carotid artery (fig. 116, No. 5) ascends the neck perpendicularly, from the right sterno-clavicular articulation to a level with the upper border of the thyroid cartilage, where it divides into the external and internal carotid.

The Left common carotid (fig. 116, No. 11) passes somewhat obliquely outwards from the arch of the aorta to the side of the neck, and thence upwards to a level with the upper border of the thyroid cartilage, where it divides like the right common carotid into the external and internal carotid.

Relations.—The right common carotid rests, first, upon the longus colli muscle, then upon the rectus anticus major, the sympathetic nerve being interposed. The inferior thyroid artery and recurrent laryngeal nerve pass behind it at its lower part. To its inner side is the trachea, recurrent laryngeal nerve, and larynx; to its outer side, and enclosed in the same sheath, the jugular vein and pneumogastric nerve; and in front the sterno-thyroid, sterno-hyoid, sterno-mastoid, omo-hyoid, and platysma muscles, and the descendens noni nerve. The left common carotid, in addition to the relations just enumerated, which are common to both, is crossed near its commencement by the left vena innominata; it lies upon the trachea; then gets to its side, and is in relation with the cesophagus and thoracic duct: to facilitate the study of these relations, I have arranged them in a tabular form.

Plan of Relations of the Common Carotid Artery.

In Front.
Platysma,
Descendens noni nerve,

Rectus anticus major,
Sympathetic,
Inferior thyroid artery,
Recurrent laryngeal nerve.
EXTERNAL CAROTID ARTERY.

Additional Relations of the Left Common Carotid.

Left vena innominata. Trachea, Arteria innominata, Pleura.
Thoracic duct. Esophagus.

EXTERNAL CAROTID ARTERY.

The *External carotid artery* ascends nearly perpendicularly from opposite the upper border of the thyroid cartilage, to the space between the neck of the lower jaw and the meatus auditorius, where it divides into the temporal and internal maxillary artery.

Relations.—*In front* it is crossed by the posterior belly of the digastricus, stylo-hyoideus, and platysma myoides muscles; by the hypoglossal nerve near its origin; higher up it is situated in the substance of the parotid gland, and is crossed by the facial nerve. *Behind* it is separated from the internal carotid by the stylo-pharyngeus and stylo-glossus muscles, glosso-pharyngeal nerve, and part of the parotid gland.

Plan of the Relations of the External Carotid Artery.

Parotid gland.

Branches.—The branches of the external carotid are eleven in number, and may be arranged into four groups, viz.

Anterior. Posterior.
1. Superior thyroid, 4. Mastoid,
2. Lingual, 5. Occipital,

Superior. Terminal.
7. Parotidean, 10. Temporal,
8. Ascending pharyngeal, 11. Internal maxillary,
The anterior branches arise from the commencement of the external carotid, within a short distance of each other. The lingual and facial bifurcate, not unfrequently, from a common trunk.

1. The Superior Thyroid Artery (the first of the branches of the external carotid) curves downwards to the thyroid gland to which it is distributed, anastomosing with its fellow of the opposite side, and with the inferior thyroid arteries. In its course it passes beneath the omo-hyoid, sterno-thyroid, and sterno-hyoid muscles.

Fig. 117.*

Branches.—Hyoid,
Superior laryngeal,
Inferior laryngeal,
Muscular.

The Hyoid branch passes forwards beneath the thyro-hyoides, and is distributed to the depressor muscles of the os hyoides near their insertion.

The Superior laryngeal pierces the thyro-hyoidean membrane, in company with the superior laryngeal nerve, and supplies the mucous membrane and muscles of the larynx, sending a branch upwards to the epiglottis.

The Inferior laryngeal is a small branch which crosses the crico-thyroidean membrane along the lower border of the thyroid cartilage. It sends branches through the membrane to supply the mucous lining of the larynx, and inosculates with its fellow of the opposite side.

The Muscular branches are distributed to the depressor muscles of the os hyoides and larynx. One of these branches crosses the sheath of the common carotid to the under surface of the sterno-mastoid muscle.

2. The Lingual artery ascends obliquely from its origin, it then passes forwards parallel with the os hyoides; thirdly, it ascends to the under surface of the tongue; and fourthly, runs forward in a serpentine direction to its tip, under the name of the ranine artery, where it terminates by inosculating with its fellow of the opposite side.

Relations.—The first part of its course rests upon the middle constrictor muscle of the pharynx, being covered in by the tendon of the digastricus and the stylo-hyoid muscle; the second is situated between the middle constrictor and hyo-glossus muscle, the latter separating it from the hypoglossal nerve; in the third part of its course it lies between the hyo-glossus and genio-hyo-glossus; and in the fourth (ranine) rests upon the lingualis to the tip of the tongue.

Branches.—Hyoid,
Dorsalis linguae,
Sublingual.

The Hyoid branch runs along the upper border of the os hyoides, and is distributed to the elevator muscles of the os hyoides near their origin, inosculating with its fellow of the opposite side.

The Dorsalis linguae ascends along the posterior border of the hyo-glossus muscle to the dorsum of the tongue, and is distributed to the tongue, the fauces, and epiglottis, anastomosing with its fellow of the opposite side.

The Sublingual branch, sometimes considered as a branch of bifurcation of the lingual, runs along the anterior border of the hyo-glossus, and is distributed to the sublingual gland and to the muscles of the
tongue. It is situated between the mylo-hyoid and genio-hyo-glos-
sus, generally accompanies Wharton’s duct for a part of its course, and
sends a branch to the frænum linguae. It is the latter branch which
affords the considerable hemorrhage which sometimes follows the
operation of snipping the frænum in children.

3. Facial artery.—The Facial artery arises a little above the
great cornu of the os hyoides, and descends obliquely to the submax-
illary gland, in which it lies embedded. It then curves around the
body of the lower jaw, close to the anterior inferior angle of the mas-
seter muscle, ascends to the angle of the mouth, and thence to the
angle of the eye, where it is named the angular artery. The facial
artery is tortuous in its course over the buccinator muscle, to accom-
modate itself to the movements of the jaws.

Relations.—Below the jaw it passes beneath the digastricus and
stylo-hyoid muscles; on the body of the lower jaw it is covered by
the platysma myoides, and at the angle of the mouth by the depressor
anguli oris and zygomatic muscles. It rests upon the submaxillary
gland, the lower jaw, buccinator, orbicularis oris, levator anguli oris,
levator labii superioris proprius, and levator labii superioris alæque
nasi.

Its branches are divided into those which are given off below the
jaw and those on the face: they may be thus arranged:—

*Below the Jaw.*—Inferior palatine,
    Submaxillary,
    Submental,
    Pterygoid.

*On the Face.*—Masseteric,
    Inferior labial,
    Inferior coronary,
    Superior coronary,
    Lateralis nasi.

The Inferior palatine branch ascends between the stylo-glossus
and stylo-pharyngeus muscles, to be distributed to the tonsil and soft
palate, and anastomoses with the posterior palatine branch of the
internal maxillary artery.

The Submaxillary are four or five branches which supply the sub-
maxillary gland.

The Submental branch runs forwards upon the mylo-hyoid muscle,
under cover of the body of the lower jaw, and anastomoses with
branches of the sublingual and inferior dental artery.

The Pterygoid branch is distributed to the internal pterygoid
muscle.

The Masseteric branches are distributed to the masseter and bucci-
nator muscles.
The *Inferior labial* branch is distributed to the muscles and integument of the lower lip.

The *Inferior coronary* runs along the edge of the lower lip, between the mucous membrane, and the orbicularis oris; it inosculates with the corresponding artery of the opposite side.

The *Superior coronary* follows the same course along the upper lip, inosculating with the opposite superior coronary artery, and at the middle of the lip it sends a branch upwards to supply the septum of the nose and the mucous membrane.

The *Lateralis nasi* is distributed to the ala and septum of the nose.

The *Inosculations* of the facial artery are very numerous; thus, it anastomoses with the sublingual branch of the lingual, with the ascending pharyngeal and posterior palatine arteries, with the inferior dental as it escapes from the mental foramen, infra-orbital at the infra-orbital foramen, transverse facial on the side of the face, and at the angle of the eye with the nasal and frontal branches of the ophthalmic artery.

The facial artery is subject to considerable variety in its extent; it not unfrequently terminates at the angle of the nose or mouth, and is rarely symmetrical on both sides of the face.

4. The *Mastoid artery* turns downwards from its origin, to be distributed to the sterno-mastoid muscle, and to the lymphatic glands of the neck; sometimes it is replaced by two small branches.

5. The *Occipital artery*, smaller than the anterior branches, passes backwards beneath the posterior belly of the digastricus, the trachelo-mastoid and sterno-mastoid muscles, to the occipital groove in the mastoid portion of the temporal bone. It then ascends between the splenius and complexus muscles, and divides into two branches which are distributed upon the occiput, anastomosing with the opposite occipital, the posterior auricular, and temporal artery. The hypoglossal nerve curves around this artery near its origin from the external carotid.

*Branches.*—It gives off only two branches deserving of name, the inferior meningeal and princeps cervicis.

The *Inferior meningeal* ascends by the side of the internal jugular vein, and passes through the foramen lacerum posterius, to be distributed to the dura mata.

The *Arteria princeps cervicis* is a large and irregular branch. It descends the neck between the complexus and semi-spinalis colli, and inosculates with the profunda cervicis of the subclavian. This branch is the means of establishing a very important collateral circulation between the branches of the carotid and subclavian, after ligature of the common carotid artery.

6. The *Posterior auricular artery* arises from the external carotid, above the level of the digastric and stylo-hyoid muscles, and
ascends beneath the lower border of the parotid gland, and behind the concha, to be distributed by two branches to the external ear and side of the head, anastomosing with the occipital and temporal arteries; some of its branches pass through fissures in the fibro-cartilage, to be distributed to the anterior surface of the pinna. The anterior auricular arteries are branches of the temporal.

**Branches.**—The posterior auricular gives off but one named branch, the *stylo-mastoid*, which enters the stylo-mastoid foramen to be distributed to the aqueductus Fallopii and tympanum.

7. The **Parotidean arteries** are four or five large branches which are given off from the external carotid whilst that vessel is situated in the parotid gland. They are distributed to the structure of the gland, their terminal branches reaching the integument and the side of the face.

8. The **Ascending pharyngeal artery**, the smallest of the branches of the external carotid arises from that trunk near its bifurcation, and ascends between the internal carotid and the side of the pharynx to the base of the skull, where it divides into two branches; *meningeal*, which enters the foramen lacerum posterius, to be distributed to the dura mater; and *pharyngeal*. It supplies the pharynx, tonsils, and Eustachian tube.

9. The **Transversalis faciei** arises from the external carotid whilst that trunk is lodged within the parotid gland; it crosses the masseter muscle, lying parallel with and a little above Stenon’s duct; and is distributed to the temporo-maxillary articulation, and to the muscles and integument on the side of the face, inosculating with the infra-orbital and facial artery. This artery is not unfrequently a branch of the temporal.

10. The **Temporal artery** is one of the two terminal branches of the external carotid. It ascends over the root of the zygoma; and, at about an inch and a half above the zygomatic arch, divides into an anterior and a posterior temporal branch. The *anterior temporal* is distributed over the front of the temple and arch of the skull, and anastomoses with the opposite anterior temporal, and with the supra-orbital and frontal artery. The *posterior temporal* curves upwards and backwards, and inosculates with its fellow of the opposite side, with the posterior auricular and occipital artery.

The trunk of the temporal artery is covered in by the parotid gland and by the attrahens aurem muscle, and rests upon the temporal fascia.

**Branches.**—Orbitar,
Anterior auricular,
Middle temporal.

The *Orbitar artery* is a small branch, not always present, which
passes forwards immediately above the zygoma, between the two layers of the temporal fascia, and inosculates beneath the orbicularis palpebrarum with the palpebral arteries.

The *Anterior auricular arteries* are distributed to the anterior portion of the pinna.

The *Middle temporal branch* passes through an opening in the temporal fascia immediately above the zygoma, and supplies the temporal muscle inosculating with the deep temporal arteries.

11. The **Internal maxillary artery**, the other terminal branch of the external carotid, has next to be examined.

**Dissection.**—The *Internal maxillary artery* passes inwards behind the neck of the lower jaw to the deep structures in the face; we require, therefore, to remove several parts for the purpose of seeing it completely. To obtain a good view of the vessel, the zygoma should be sawn across in front of the external ear, and the malar bone near the orbit. Turn down the zygomatic arch with the masseter muscle. In doing this a small artery and nerve will be seen crossing the sigmoid notch of the lower jaw, and entering the masseter muscle (the masseteric). Cut away the tendon of the temporal muscle from its insertion into the coronoid process and turn it upwards towards its origin; some vessels will be seen entering its under surface; these are the *deep temporal*. Then saw the ramus of the jaw across its middle, and dislocate it from its articulation with the temporal bone. Be careful in doing this to carry the blade of the knife close to the bone, lest any branches of nerves should be injured. Next raise this portion of bone, and with it the external pterygoid muscle. The artery, together with the deep branches of the inferior maxillary nerve, will be seen lying upon the pterygoid muscles. These are to be carefully freed from fat and areolar tissue, and then examined.

This artery (fig. 117, No. 12) commences in the substance of the parotid gland, opposite the meatus auditorius externus; it passes in the first instance horizontally forwards behind the neck of the lower jaw; next, curves around the lower border of the external pterygoid muscle near its origin, and ascends obliquely forwards upon the outer side of that muscle; it then passes between the two heads of the external pterygoid and enters the pterygo-maxillary fossa. Occasionally it passes between the two pterygoid muscles, without appearing on the outer surface of the external pterygoid. In consideration of its course this artery may be divided into three portions: maxillary, pterygoid, and sphenomaxillary.

**Relations.**—The *maxillary* portion is situated between the ramus of the jaw and the internal lateral ligament, lying parallel with the auricular nerve; the *pterygoid* portion between the external pterygoid muscle, and the masseter and temporal muscle. The *pterygo-maxillary* portion lies between the two heads of the external pterygoid muscle, and in the sphenomaxillary fossa is in relation with Meckel’s ganglion.
INTERNAL MAXILLARY ARTERY.

Branches.

Maxillary Portion.

Tympanic,
Inferior dental,
Arteria meningea media,
Arteria meningea parva.

Pterygoid Portion.

Deep temporal branches,
External pterygoid,
Internal pterygoid,
Masseteric,
Buccal.

Pterygo-maxillary Portion.

Superior dental,
Infra-orbital,
Pterygo-palatine,
Spheno-palatine,
Posterior palatine,
Vidian.

The Tympanic branch is small and not likely to be seen in an ordinary dissection; it is distributed to the temporo-maxillary articulation and meatus, and passes into the tympanum through the fissura Glasseri.

The Inferior dental descends to the dental foramen, and enters the canal of the lower jaw in company with the dental nerve. Opposite the bicuspid teeth it divides into two branches, one of which is continued onwards within the bone as far as the symphysis, to supply the incisor teeth, while the other escapes with the nerve at the mental foramen, and anastomoses with the inferior labial and submental branch of the facial. It supplies the teeth of the lower jaw, sending small branches along the canals in their roots.

The Arteria meningea media ascends behind the temporo-maxillary articulation to the foramen spinosum in the sinus process of the sphenoid bone, and, entering the cranium, divides into an anterior and a posterior branch. The anterior branch crosses the great ala of the sphenoid to the groove or canal in the anterior inferior angle of the parietal bone, and divides into branches, which ramify upon the external surface of the dura mater, and anastomose with corresponding branches from the opposite side. The posterior branch crosses the squamous portion of the temporal bone, to the posterior part of the dura mater and cranium. The branches of the artesia meningea media are distributed chiefly to the bones of the skull; in the middle fossa it sends a small branch through the hiatus Fallopii to the facial nerve.

The Meningea parva is a small branch which ascends to the foramen ovale, and passes into the skull to be distributed to the Casserian ganglion and dura mater. It gives off a twig to the nasal fossa and soft palate.

The Muscular branches are distributed, as their names imply, to the five muscles of the maxillary region; the temporal branches (temporales profundae) are two in number.

The Superior dental artery is given off from the internal maxillary,
just as that vessel is about to make its turn into the sphenomaxillary fossa. It descends upon the tuberosity of the superior maxillary bone, and sends its branches through several small foramina to supply the posterior teeth of the upper jaw, and the antrum. The terminal branches are continued forwards upon the alveolar process, to be distributed to the gums and to the sockets of the teeth.

The Infra-orbital would appear, from its size, to be the proper continuation of the artery. It runs along the infra-orbital canal with the superior maxillary nerve, sending branches into the orbit and downwards through canals in the bone, to supply the mucous lining of the antrum and the teeth of the upper jaw, and escapes from the infraorbital foramen. The branch which supplies the incisor teeth is the anterior dental artery; on the face the infraorbital inosculates with the facial and transverse facial arteries.

The Pterygo-palatine is a small branch which passes through the pterygo-palatine canal, and supplies the upper part of the pharynx and Eustachian tube.

The Spheno-palatine, or nasal, enters the superior meatus of the nose through the sphenopalatine foramen in company with the nasal branches of Meckel’s ganglion, and divides into two branches; one of which is distributed in the mucous membrane of the septum, while the other supplies the mucous membrane of the lateral wall of the nares, together with the sphenoid and ethmoid cells.

The Posterior palatine artery descends along the posterior palatine canal, in company with the posterior palatine branches of Meckel’s ganglion, to the posterior palatine foramen; it then curves forwards lying in a groove upon the bone, and is distributed to the palate. While in the posterior palatine canal it sends a branch backwards, through the small posterior palatine foramen to supply the soft palate, and anteriorly it distributes a branch to the anterior palatine canal, which reaches the nares and inosculates with the branches of the sphenopalatine artery.

The Vidian branch passes backwards along the pterygoid canal, and is distributed to the sheath of the Vidian nerve, and to the Eustachian tube.

INTERNAL CAROTID ARTERY.

The internal carotid artery curves slightly outwards from the bifurcation of the common carotid, and then ascends nearly perpendicularly through the maxillo-pharyngeal space* to the carotid foramen in the petrous bone. It next passes inwards, along the carotid canal, forwards by the side of the sella turcica, and upwards by the anterior clinoid process, where it pierces the dura mater and divides into three terminal branches. The course of this artery is remarkable for the number of angular curves which it forms; one or two of these flexures

* For the boundaries of this space see page 189.
are sometimes seen in the cervical portion of the vessel near the base of the skull; and by the side of the sella turcica it resembles the italic letter s, placed horizontally.

Relations.—In consideration of its connections, the artery is divisible into a cervical, petrous, cavernous, and cerebral portion. The Cervical portion is in relation posteriorly with the rectus anticus major, sympathetic nerve, pharyngeal and laryngeal nerves which cross behind it, and near the carotid foramen with the glosso-pharyngeal, pneumogastric and lingual nerves, and partially with the internal jugular vein. Internally it is in relation with the side of the pharynx, the tonsil, and the ascending pharyngeal artery. Externally with the internal jugular vein, glosso-pharyngeal, pneumogastric, and hypoglossal nerves; and in front with the stylo-glossus, and stylo-pharyngeus muscle, glosso-pharyngeal nerve, and parotid gland.

Plan of the relations of the cervical portion of the internal carotid artery.

In Front.
Parotid gland,
Stylo-glossus muscle,
Stylo-pharyngeus muscle,
Glosso-pharyngeal nerve.

Internally.
Pharynx,
Tonsil,
Ascending pharyngeal artery.

Internal Carotid Artery.

Externally.
Jugular vein,
Glosso-pharyngeal,
Pneumogastric,
Hypoglossal nerve.

Behind.
Superior cervical ganglion,
Pneumogastric nerve,
Glosso-pharyngeal,
Pharyngeal nerve,
Superior laryngeal nerve,
Sympathetic nerve,
Rectus anticus major.

The Petrous portion is separated from the bony wall of the carotid canal by a lining of dura mater; it is in relation with the carotid plexus, and is covered in by the Casserian ganglion.

The Cavernous portion is situated in the inner wall of the cavernous sinus, and is in relation by its outer side with the lining membrane of the sinus, the sixth nerve, and the ascending branches of the carotid plexus. The third, fourth, and ophthalmic nerves are placed in the outer wall of the cavernous sinus, and are separated from the artery by the lining membrane of the sinus.

The Cerebral portion of the artery is enclosed in a sheath of the arachnoid, and is in relation with the optic nerve. At its point of division it is situated in the fissure of Sylvius.
Branches.—The cervical portion of the internal carotid gives off no branches: from the other portions are derived the following:—

- Tympanic,
- Anterior meningeal,
- Ophthalmic,
- Anterior cerebral,
- Middle cerebral,
- Posterior communicating,
- Choroidean.

The Tympanic is a small branch which enters the tympanum through a minute foramen in the carotid canal.

The Anterior meningeal is distributed to the dura mater and Casserian ganglion.

The Ophthalmic artery arises from the cerebral portion of the internal carotid, and enters the orbit through the foramen opticum, immediately to the outer side of the optic nerve. It then crosses the optic nerve to the inner wall of the orbit, and runs along the lower border of the superior oblique muscle, to the inner angle of the eye, where it divides into two terminal branches, the frontal and nasal.

Branches.—The branches of the ophthalmic artery may be arranged into two groups: first, those distributed to the orbit and surrounding parts; and secondly, those which supply the muscles and globe of the eye. They are—

**First Group.**
- Lachrymal,
- Supra-orbital,
- Posterior ethmoidal,
- Anterior ethmoidal,
- Palpebral,
- Frontal,
- Nasal.

**Second Group.**
- Muscular,
- Anterior ciliary,
- Ciliary short and long,
- Centralis retinae.

The Lachrymal is the first branch of the ophthalmic artery, and is usually given off immediately before that artery enters the optic foramen. It follows the course of the lachrymal nerve, along the upper border of the external rectus muscle, and is distributed to the lachrymal gland. The small branches which escape from the gland supply the conjunctiva and upper eyelid. The lachrymal artery gives off a malar branch which passes through the malar bone into the temporal fossa and inosculates with the deep temporal arteries, while some of its branches become subcutaneous on the cheek and anastomose with the transverse facial.

The Supra-orbital artery follows the course of the frontal nerve, resting on the levator palpebræ muscle; it passes through the supra-orbital foramen and divides into a superficial and deep branch, which are distributed to the muscles and integument of the forehead and to
the pericranium. At the supra-orbital foramen it sends a branch in-
wards to the diploë.

The Ethmoidal arteries, posterior and anterior, pass through the
ethmoidal foramina, and are distributed to the falx cerebri and to the
ethmoidal cells and nasal fossæ. The latter accompanies the nasal
nerve.

The Palpebral arteries, superior and inferior, are given off from the
ophthalmic, near the inner angle of the orbit; they encircle the eye-
lids, forming a superior and an inferior arch near the borders of the
lids, between the orbicularis palpebrarum and tarsal cartilage. At the
outer angle of the eyelids the superior palpebral inosculates with the
orbitar branch of the temporal artery. The inferior palpebral artery
sends a branch to the nasal duct.

The Frontal artery, one of the terminal branches of the ophthalmic,
emerges from the orbit at its inner angle, and ascends along the mid-
de of the forehead. It is distributed to the integument, muscles, and
pericranium.

The Nasal artery, the other terminal branch of the ophthalmic,
passes out of the orbit above the tendo oculi, and divides into two
branches; one of which inosculates with the angular artery, while the
other, the dorsalis nasi, runs along the ridge of the nose and is distri-
buted to the entire surface of that organ. The nasal artery sends a
small branch to the lacrimal sac.

The Muscular branches, usually two in number, superior and in-
ferior, supply the muscles of the orbit; and upon the anterior aspect
of the globe of the eye give off the anterior ciliary arteries, which
pierce the sclerotic near its margin of connection with the cornea, and
are distributed to the iris. It is the congestion of these vessels that
gives rise to the vascular zone around the cornea in iritis.

The Ciliary arteries are divisible into three groups, short, long, and
anterior.

The Short ciliary are very numerous; they pierce the sclerotic
around the entrance of the optic nerve, and supply the choroid coat
and ciliary processes. The long ciliary, two in number, pierce the
sclerotic on opposite sides of the globe of the eye, and pass forwards
between it and the choroid to the iris. They form an arterial circle
around the circumference of the iris by inosculating with each other,
and from this circle branches are given off which ramify in the sub-
stance of the iris, and form a second circle around the pupil. The an-
terior ciliary are branches of the muscular arteries; they terminate in
the great arterial circle of the iris.

The Centralis retinae artery pierces the optic nerve obliquely, and
passes forwards in the centre of its cylinder to the retina, where it di-
vides into branches, which ramify in the inner layer of that membrane.
It supplies the retina, hyaloid membrane, and zonula ciliaris; and, by
means of a branch sent forwards through the centre of the vitreous
humour in a tubular sheath of the hyaloid membrane, the capsule of
the lens.
The Anterior cerebral artery passes forwards in the great longitudinal fissure between the two hemispheres of the brain; then curves backwards along the corpus callosum to its posterior extremity. It gives branches to the olfactory and optic nerves, to the under surface of the anterior lobes, the third ventricle, the corpus callosum, and the inner surface of the hemispheres. The two anterior cerebral arteries are connected soon after their origin by a short anastomosing trunk, the anterior communicating.

The Middle cerebral artery, larger than the preceding, passes outwards along the fissure of Sylvius, and divides into three principal branches, which supply the anterior and middle lobes, and the island of Reil. Near its origin it gives off the numerous small branches which enter the substantia perforata, to be distributed to the corpus striatum.

The Posterior Communicating artery, very variable in size, sometimes double, and sometimes altogether absent, passes backwards and inosculates with the posterior cerebral, a branch of the basilar artery. Occasionally it is so large as to take the place of the posterior cerebral artery.

The Choroidean is a small branch which is given off from the internal carotid, near the origin of the posterior communicating artery, and passes beneath the edge of the middle lobe of the brain to enter the descending cornu of the lateral ventricle. It is distributed to the choroid plexus, and to the walls of the middle cornu.

The Subclavian artery, on the right side, arises from the arteria innominata, opposite the sterno-clavicular articulation, and on the left, from the arch of the aorta. The right is consequently shorter than the left, and is situated nearer to the anterior wall of the chest; it is also somewhat greater in diameter, from being a branch of a branch, in place of a division from the main trunk.

The course of the subclavian artery is divisible, for the sake of precision and surgical observation, into three portions. The first portions of the right and left arteries differ in their course and relations in correspondence with their dissimilarity of origin. The other two portions are precisely alike on both sides.

The first portion, on the right side, ascends obliquely outwards to the inner border of the scalenus anticus. On the left side it ascends perpendicularly to the inner border of that muscle. The second portion curves outwards behind the scalenus anticus; and the third portion passes downwards and outwards beneath the clavicle, to the lower border of the first rib, where it becomes the axillary artery.

Relations.—The first portion, on the right side, is in relation in front with the internal jugular and subclavian vein at their point of junction, and is crossed by the pneumogastric nerve, cardiac nerves,
and phrenic nerve. *Behind and beneath* it is invested by the pleura, is crossed by the right recurrent laryngeal nerve and vertebral vein, and is in relation with the transverse process of the seventh cervical vertebra. The *first portion* on the *left side* is in relation in front with the pleura, the vena innominata, the pneumogastric and phrenic nerves (which lie parallel to it), and the left carotid artery. To its *inner side* is the oesophagus; to its *outer side* the pleura; and *behind*, the thoracic duct, longus colli, and vertebral column.

Plan of the relations of the *first portion* of the *Right* Subclavian Artery.

*In Front.*
- Internal jugular vein,
- Subclavian vein,
- Pneumogastric nerve,
- Cardiac nerves,
- Phrenic nerve.

*Right Subclavian Artery.*

*Behind and Beneath.*
- Pleura,
- Recurrent laryngeal nerve,
- Vertebral vein,
- Transverse process of 7th cervical vertebra.

Plan of the relations of the *first portion* of the *Left* Subclavian Artery.

*In Front.*
- Pleura,
- Vena innominata,
- Pneumogastric nerve,

The *Vertebral* artery is the first and the largest of the branches of the subclavian artery; it ascends through the foramina in the transverse processes of all the cervical vertebrae, excepting the last; then winds backwards around the articulating process of the atlas; and, piercing the dura mater, enters the skull through the foramen magnum. The two arteries unite at the lower border of the pons Varolii, to form the *basilar artery*. In the foramina of the transverse processes of the vertebræ the artery lies in front of the cervical nerves.

Dr. John Davy* has observed that, when the vertebral arteries differ in size, the left is generally the larger; thus in ninety-eight cases he found the left vertebral the larger twenty-six times, and the right only eight. In the same number of cases he found a small band stretching across the cylinder of the basilar artery, near the junction of the two vertebral arteries, seventeen times, and in a few instances a small communicating trunk between the two vertebral arteries previously to their union. I have several times seen this communicating branch, and have a preparation now before me in which it is exhibited.

The *Basilar* artery, so named from its position at the base of the brain, runs forwards to the anterior border of the pons Varolii, where it divides into four ultimate branches, two to either side.

**Branches.**—The branches of the vertebral and basilar arteries are the following:—

\{ 
Lateral spinal,
Posterior meningeal,
Vertebral,  
Anterior spinal,
Posterior spinal,
Inferior cerebellar,
Transverse,
Basilar,  
Superior cerebellar,
Posterior cerebral.
\}

* Edinburgh Medical and Surgical Journal, 1839.*
The Lateral spinal branches enter the invertebral foramina, and are distributed to the spinal cord and to its membranes. Where the vertebral artery curves around the articular process of the atlas, it gives off several muscular branches.

The Posterior meningeal are one or two small branches which enter the cranium through the foramen magnum, to be distributed to the dura mater of the cerebellar fossae, and to the falx cerebelli. One branch, described by Soemmering, passes into the cranium along the first cervical nerve.

The Anterior spinal is a small branch which unites with its fellow of the opposite side, on the front of the medulla oblongata. The artery formed by the union of these two vessels descends along the anterior aspect of the spinal cord, to which it distributes branches.

The Posterior spinal winds around the medulla oblongata to the posterior aspect of the cord, and descends on either side, communicating very freely with the spinal branches of the intercostal and lumbar arteries. Near its commencement it sends a branch upwards to the fourth ventricle.

The Inferior cerebellar arteries wind around the upper part of the medulla oblongata to the under surface of the cerebellum, to which they are distributed. They pass between the filaments of origin of the hypoglossal nerve in their course, and Anastomose with the superior cerebellar arteries.

The Transverse branches of the basilar artery supply the pons Varolii, and adjacent parts of the brain. One of these branches, larger than the rest, passes along the crus cerebelleri to be distributed to the anterior border of the cerebellum. This may be called the middle cerebellar artery.

The Superior cerebellar arteries, two of the terminal branches of the basilar, wind around the crus cerebri on each side in relation with the fourth nerve, and are distributed to the upper surface of the cerebellum inosculating with the inferior cerebellar. This artery gives off a small branch which accompanies the seventh pair of nerves into the meatus auditorius internus.

The Posterior cerebral arteries, the other two terminal branches of the basilar, wind around the crus cerebri at each side, and are distributed to the posterior lobes of the cerebrum. They are separated from the superior cerebellar artery, near their origin, by the third pair of nerves, and are in close relation with the fourth pair in their course around the crura cerebri. Anteriorly, near their origin, they give off a tuft of small vessels which enter the locus perforatus, and they receive the posterior communicating arteries from the internal carotid. They also send a branch to the velum interpositum and plexus choroïdes.

The communications established between the anterior cerebral arteries in front, and the internal carotids and posterior cerebral arteries behind, by the communicating arteries, constitute the circle of Willis. This remarkable communication at the base of the brain is
formed by the anterior communicating branch, anterior cerebals, and internal carotid arteries in front, and by the posterior communicating, posterior cerebals, and basilar artery behind.

The **Thyroid axis** is a short trunk which divides almost immedi-

ately after its origin into four branches, some of which are occasionally branches of the subclavian artery itself.

The Inferior Thyroid Artery ascends obliquely in a serpentine course behind the sheath of the carotid vessels, to the inferior part of thyroid gland, to which it is distributed; it sends branches also to the trachea, lower part of the larynx, and oesophagus. It is in relation with the middle cervical ganglion of the sympathetic, which lies in front of it.

The Supra-scapular Artery (transversalis humeri) passes obliquely outwards behind the clavicle, and over the ligament of the supra-scapular notch, to the supra-spinatus fossa. It crosses in its course the scalenus anticus muscle, phrenic nerve, and subclavian artery, is distributed to the muscles on the dorsum of the scapula, and inosculates with the posterior scapular, and beneath the acromion process with the dorsal branch of the subscapular artery. At the supra-scapular notch it sends a large branch to the trapezius muscle. The supra-scapular artery is not unfrequently a branch of the subclavian.

The Posterior Scapular Artery (transversalis colli) passes transversely across the subclavian triangle at the root of the neck, to the superior angle of the scapula. It then descends along the posterior border of that bone to its inferior angle, where it inosculates with the subscapular artery, a branch of the axillary. In its course across the neck it passes in front of the scalenus anticus, and across the brachial plexus; in the rest of its course it is covered in by the trapezius, levator anguli scapulae, rhomboideus minor, and rhomboideus major muscles. Sometimes it passes behind the scalenus anticus, and between the nerves, which constitute the brachial plexus. This artery, which is very irregular in its origin, proceeds more frequently from the third portion of the subclavian artery than from the first.

The posterior scapular gives branches to the neck, and opposite the angle of the scapula inosculates with the profunda cervicis. It supplies the muscles along the posterior border of the scapula, and establishes an important anastomotic communication between the branches of the external carotid, subclavian, and axillary arteries.

The Superficialis Cervicis Artery (cervicalis anterior) is a small vessel, which ascends upon the anterior tubercles of the transverse processes of the cervical vertebra, lying in the groove between the scalenus anticus and rectus anticus major. It is distributed to the deep muscles and glands of the neck, and sends branches through the intervertebral foramina to supply the spinal cord and its membranes.

The Profunda Cervicis (cervicalis posterior) passes backwards between the transverse processes of the seventh cervical and first dorsal vertebra, and then ascends the back part of the neck, between the
complexus and semi-spinalis colli muscles. It inosculates above with the princeps cervicis of the occipital artery, and below, by a descending branch, with the posterior scapular.

The Superior intercostal artery descends behind the pleura upon the necks of the first two ribs, and inosculates with the first aortic intercostal. It gives off two branches which supply the first two intercostal spaces.

The Internal mammary artery descends by the side of the sternum, resting upon the costal cartilages, to the diaphragm; it then pierces the anterior fibres of the diaphragm; and enters the sheath of the rectus, where it inosculates with the epigastric artery, a branch of the external iliac. In the upper part of its course it is crossed by the phrenic nerve, and lower down lies between the triangularis sterni and the internal intercostal muscles.

The branches of the internal mammary are,—

Anterior intercostal,
Mammary,
Comes nervi phrenici,
Mediastinal,
Pericardiac,
Musculo-phrenic.

The anterior intercostals supply the intercostal muscles of the front of the chest, and inosculate with the aortic intercostal arteries. Each of the first three anterior intercostals gives off a large branch to the mammary gland, which anastomoses freely with the thoracic branches of the axillary artery; the corresponding branches from the remaining intercostals supply the integument and pectoralis major muscle. There are usually two anterior intercostal arteries in each space.

The Comes nervi phrenici is a long and slender branch which accompanies the phrenic nerve.

The mediastinal and pericardiac branches are small vessels distributed to the anterior mediastinum, the thymus gland, and pericardium.

The Musculo-phrenic artery winds along the attachment of the diaphragm to the ribs, supplying that muscle and sending branches to the inferior intercostal spaces. "The mammary arteries," says Dr. Harrison, "are remarkable for the number of their inosculations, and for the distant parts of the arterial system which they serve to connect. They anastomose with each other, and their inosculations, with the thoracic aorta, encircle the thorax. On the parietes of this cavity their branches connect the axillary and subclavian arteries; on the diaphragm they form a link in the chain of inosculations between the subclavian artery and abdominal aorta, and in the parietes of the abdomen they form an anastomosis most remarkable for the distance be-
tween those vessels which it serves to connect; namely, the arteries of the superior and inferior extremities."

Varieties of the subclavian Arteries.—Varieties in these arteries are rare; that which most frequently occurs is the origin of the right subclavian, from the left extremity of the arch of the aorta, below the left subclavian artery. The vessel, in this case, curves behind the oesophagus and right carotid artery, and sometimes between the oesophagus and trachea, to the upper border of the first rib on the right side of the chest, where it assumes its ordinary course. In a case* of subclavian aneurism on the right side, above the clavicle, which happened during the summer of 1839, Mr. Liston proceeded to perform the operation of tying the carotid and subclavian arteries at their point of division from the innominata. Upon reaching the point where the bifurcation should have existed, he found that there was no subclavian artery. With that admirable self-possession which distinguishes this eminent surgeon in all cases of emergency, he continued his dissection more deeply, towards the vertebral column, and succeeded in securing the artery. It was ascertained after death, that the arteria innominata was extremely short, and that the subclavian was given off within the chest from the posterior aspect of its trunk, and pursued a deep course to the upper margin of the first rib. In a preparation which was shewn to me in Heidelberg some years since by Professor Tiedemann, the right subclavian artery arose from the thoracic aorta, as low down as the fourth dorsal vertebra, and ascended from that point to the border of the first rib. Varieties in the branches of the subclavian are not unfrequent; the most interesting is the origin of the left vertebral, from the arch of the aorta, of which I possess several preparations.

AXILLARY ARTERY.

The axillary artery forms a gentle curve through the middle of the axillary space from the lower border of the first rib to the lower border of the latissimus dorsi, where it becomes the brachial.

Relations.—After emerging from beneath the margin of the costocoracoid membrane, it is in relation with the axillary vein, which lies at first to the inner side, and then in front of the artery. Near the middle of the axilla it is embraced by the two heads of the median nerve, and is covered in by the pectoral muscles. Upon the inner or thoracic side it is in relation, first, with the first intercostal muscle; it next rests upon the first serration of the serratus magnus; and is then separated from the chest by the brachial plexus of nerves. By its outer or humeral side it is at first separated from the brachial plexus by a triangular cellular interval; it next rests against the tendon of the subscapularis muscle; and thirdly, upon the coracobrachialis muscle.

* This case is recorded in the Lancet, vol. i. 1839-40, pp. 37 and 419.
The axillary and brachial artery, with their branches. 1. The deltoid muscle. 2. The biceps. 3. The tendinous process given off from the tendon of the biceps, to the deep fascia of the fore-arm. It is this process which separates the median basilic vein from the brachial artery. 4. The outer border of the brachialis anticus muscle. 5. The supinator longus. 6. The coraco-brachialis. 7. The middle portion of the triceps muscle. 8. Its inner head. 9. The axillary artery. 10. The brachial artery;—a dark line marks the limit between these two vessels. 11. The thoracica acromialis artery dividing into its three branches; the number rests upon the coracoid process. 12. The superior and inferior thoracic arteries. 13. The serratus magnus muscle. 14. The subscapular artery. The posterior circumflex and thoracica axillaris branches are seen in the figure between the inferior thoracic and subscapular. The anterior circumflex is observed, between the two heads of the biceps, crossing the neck of the humerus. 15. The superior profunda artery. 16. The inferior profunda. 17. The anastomotica magna inosculating inferiorly with the anterior ulnar recurrent. 18. The termination of the superior profunda, inosculating with the radial recurrent in the interspace between the brachialis anticus and supinator longus.
The relations of the axillary artery may be thus arranged:—

**In Front.** | **Inner or Thoracic Side.** | **Outer or Humeral Side.**
---|---|---
Pectoralis major, | First intercostal muscle, | Plexus of nerves,
Pectoralis minor, | First serration of serratus magnus, | Tendon of subscapularis,

**Branches.**—The branches of the Axillary artery are seven in number:—

Thoracica acromialis,
Superior thoracic,
Inferior thoracic,
Thoracica axillaris,
Subscapular,
Circumflex anterior,
Circumflex posterior.

The thoracica acromialis and superior thoracic are found in the triangular space above the pectoralis minor. The inferior thoracic and thoracica axillaris, below the pectoralis minor. And the three remaining branches below the lower border of the subscapularis.

The Thoracica acromialis is a short trunk which ascends to the space above the pectoralis minor muscle, and divides into three branches, thoracic, which is distributed to the pectoral muscles and mammary gland; acromial, which passes outwards to the acromion, and inosculates with branches of the supra-scapular artery; and descending, which follows the interspace between the deltoid and pectoralis major muscles, and is in relation with the cephalic vein.

The Superior thoracic (short) frequently arises by a common trunk with the preceding; it runs along the upper border of the pectoralis minor, and is distributed to the pectoral muscles and mammary gland, inosculating with the intercostal and mammary arteries.

The Inferior thoracic (long external mammary) descends along the lower border of the pectoralis minor to the side of the chest. It is distributed to the pectoralis major and minor, serratus magnus, and subscapularis muscle, to the axillary glands and mammary gland; inosculating with the superior thoracic, intercostal, and mammary arteries.

The Thoracica axillaris is a small branch distributed to the plexus of nerves and glands in the axilla. It is frequently derived from one of the other thoracic branches.

The Subscapular artery, the largest of the branches of the axillary, runs along the lower border of the subscapularis muscle, to the inferior angle of the scapula, where it inosculates with the posterior scapular, a branch of the subclavian. It supplies, in its course, the muscles on the under surface and inferior border of the scapula, and the side of the
chest. At about an inch and a half from the axillary, it gives off a large branch, the dorsal scapula, which passes backwards through the triangular space bounded by the teres minor, teres major, and scapular head of the triceps, and beneath the infra-spinatus to the dorsum of the scapula, where it is distributed, inosculating with the supra-scapular and posterior scapular arteries.

The Circumflex arteries wind around the neck of the humerus. The anterior, very small, passes beneath the coraco-brachialis and short head of the biceps, and sends a branch upwards along the bicipital groove to supply the shoulder-joint.

The Posterior circumflex, of larger size, passes backwards through the quadrangular space bounded by the teres minor and major, the scapular head of the triceps and the humerus, and is distributed to the deltid muscle and joint. Sometimes this artery is a branch of the superior profunda of the brachial. It then ascends behind the tendon of the teres major, and is distributed to the deltid without passing through the quadrangular space. The posterior circumflex artery sends branches to the shoulder-joint.

Varieties of the axillary Artery.—The most frequent peculiarity of this kind is the division of the vessel into two trunks of equal size: a muscular trunk, which gives off some of the ordinary axillary branches and supplies the upper arm, and a continued trunk, which represents the brachial artery. The next most frequent variety is the high division of the ulnar which passes down the arm by the side of the brachial artery, and superficially to the muscles proceeding from the inner condyle, to its ordinary distribution in the hand. In this course it lies immediately beneath the deep fascia of the fore-arm, and may be seen and felt pulsating beneath the integument. The high division of the radial from the axillary is rare. In one instance, I saw the axillary artery divide into three branches of nearly equal size, which passed together down the arm, and at the bend of the elbow resolved themselves into radial, ulnar, and interosseous. But the most interesting variety, both in a physiological and surgical sense, is that described by Dr. Quain, in his "Elements of Anatomy." "I found in the dissecting-room, a few years ago, a variety not hitherto noticed; it was at first taken for the ordinary high division of the ulnar artery. The two vessels descended from the point of division at the border of the axilla, and lay parallel with one another in their course through the arm; but instead of diverging, as is usual, at the bend of the elbow, they converged, and united so as to form a short trunk which soon divided again into the radial and ulnar arteries in the regular way." In a subject, dissected by myself, this variety existed in both arms; and I have seen several instances of a similar kind.
BRACHIAL ARTERY.

The Brachial artery passes down the inner side of the arm, from the lower border of the latissimus dorsi to the bend of the elbow, where it divides into the radial and ulnar arteries.

Relations.—In its course downwards, it rests upon the coracobrachialis muscle, internal head of the triceps, brachialis anticus, and the tendon of the biceps. To its inner side is the ulnar nerve; to the outer side, the coraco-brachialis and biceps muscles; in front it has the basilic vein, and is crossed by the median nerve. Its relations, within its sheath, are the venæ comites.

Plan of the relations of the Brachial Artery.

In Front.

Coraco-brachialis,
Brachialis anticus,
Tendon of Biceps.

The branches of the brachial artery are, the—

Superior profunda,
Inferior profunda,
Anastomotica magna,
Muscular.

The Superior profunda arises opposite the lower border of the latissimus dorsi, and winds around the humerus, between the triceps and the bone, to the space between the brachialis anticus and supinator longus, where it inosculates with the radial recurrent branch. It accompanies the musculo-spiral nerve. In its course it gives off the posterior articular artery, which descends to the elbow-joint, and a more superficial branch which inosculates with the interosseous articular artery.

The Inferior profunda arises from about the middle of the brachial artery, and descends to the space between the inner condyle and olecranon in company with the ulnar nerve, where it inosculates with the posterior ulnar recurrent.

The Anastomotica magna is given off nearly at right angles from the
The arteries of the fore-arm. 1. The lower part of the biceps muscle. 2. The inner condyle of the humerus with the humeral origin of the pronator radii teres and flexor carpi radialis divided across. 3. The deep portion of the pronator radii teres. 4. The supinator longus muscle. 5. The flexor longus pollicis. 6. The pronator quadratus. 7. The flexor profundus digitorum. 8. The flexor carpi ulnaris. 9. The annular ligament with the tendons passing beneath it into the palm of the hand; the figure is placed on the tendon of the palmaris longus muscle, divided close to its insertion. 10. The brachial artery. 11. The anastomotica magna inosculating superiorly with the inferior profunda, and inferiorly with the anterior ulna recurrent. 12. The radial artery. 13. The radial recurrent artery inosculating with the termination of the superior
brachial, at about two inches above the joint. It passes directly inwards, and divides into two branches which inosculate with the anterior and posterior ulnar recurrent arteries and with the inferior profunda.

The Muscular branches are distributed to the muscles in the course of the artery, viz. to the coraco-brachialis, biceps, deltoid, brachialis anticus and triceps.

Varieties of the brachial Artery.—The most frequent peculiarity in the distribution of branches from this artery is the high division of the radial, which arises generally from about the upper third of the brachial artery, and descends to its normal position at the bend of the elbow. The ulnar artery sometimes arises from the brachial at about two inches above the elbow, and pursues either a superficial or deep course to the wrist; and, in more than one instance, I have seen the interosseous artery arise from the brachial a little above the bend of the elbow. The two profunda arteries occasionally arise by a common trunk, or there may be two superior profundæ.

RADIAL ARTERY.

The Radial artery, one of the divisions of the brachial, appears from its direction to be the continuation of that trunk. It runs along the radial side of the fore-arm, from the bend of the elbow to the wrist; it there turns around the base of the thumb, beneath its extensor tendons, and passes between the two heads of the first dorsal interosseous muscle, into the palm of the hand. It then crosses the metacarpal bones to the ulnar side of the hand, forming the deep palmar arch, and terminates by inosculating with the superficial palmar arch.

In the upper half of its course, the radial artery is situated between the supinator longus muscle, by which it is overlapped superiorly, and the pronator radii teres; in the lower half, between the tendons of the supinator longus and flexor carpi radialis. It rests in its course downwards, upon the supinator brevis, pronator radii teres, radial origin of the flexor sublimis, flexor longus pollicis, and pronator quadratus; and is covered in by the integument and fascia. At the wrist it is situated in contact with the dorsal carpal ligaments and beneath the extensor tendons of the thumb; and, in the palm of the hand, beneath the flexor tendons. It is accompanied by venae comites throughout its course, and by its middle third is in close relation with the radial nerve.

profunda. 14. The superficialis vole. 15. The ulnar artery. 16. Its superficial palmar arch giving off digital branches to three fingers and a half. 17. The magna pollicis and radialis indicis arteries. 18. The posterior ulnar recurrent. 19. The anterior interosseous artery. 20. The posterior interosseous, as it is passing through the interosseous membrane.
Plan of the *relations* of the Radial Artery in the Fore-arm.

**In Front.**
Deep fascia,

Pronator radii teres,  
Flexor sublimis digitorum,  
Flexor longus pollicis,  
Pronator quadratus,  
Wrist-joint.

The *Branches* of the radial artery may be arranged into three groups, corresponding with the three regions, the fore-arm, the wrist, and the hand; they are—

*Fore-arm,* 
{ Recurrent radial,  
Muscular.  
Superficialis volsæ,  
Carpalis anterior,  
Wrist,  
Carpalis posterior,  
Metacarpalis,  
Dorsales pollicis.  
Hand,  
Princeps pollicis,  
Radialis indicis,  
Interosseus,  
Perforantes.

The *Recurrent* branch is given off immediately below the elbow; it ascends in the space between the supinator longus and brachialis an- ticus to supply the joint, and inosculates with the terminal branches of the superior profunda. This vessel gives off numerous muscular branches.

The *Muscular branches* are distributed to the muscles on the radial side of the fore-arm.

The *Superficialis volsæ* is given off from the radial artery while at the wrist. It passes between the fibres of the abductor pollicis muscle, and inosculates with the termination of the ulnar artery, completing the superficial palmar arch. This artery is very variable in size, being sometimes as large as the continuation of the radial, and at other times a mere muscular ramusculus, or entirely wanting; when of large size it supplies the palmar side of the thumb and the radial side of the index finger.
The Carpal branches are intended for the supply of the wrist, the anterior carpal in front, and the posterior, the larger of the two, behind. The carpalis posterior crosses the carpus transversely to the ulnar border of the hand, where it inosculates with the posterior carpal branch of the ulnar artery. Superiorly it sends branches which inosculate with the termination of the anterior interosseous artery; inferiorly, it gives off posterior interosseous branches, which anastomose with the perforating branches of the deep palmar arch, and then run forward upon the dorsal interossei muscles.

The Metacarpal branch runs forward on the second dorsal interosseous muscle, and inosculates with the digital branch of the superficial palmar arch, which supplies the adjoining sides of the index and middle fingers. Sometimes it is of large size, and the true continuation of the radial artery.

The Dorsales pollicis are two small branches which run along the sides of the dorsal aspect of the thumb.

The Princeps pollicis descends along the border of the metacarpal bone, between the abductor indicis and adductor pollicis to the base of the first phalanx, where it divides into two branches, which are distributed to the two sides of the palmar aspect of the thumb.

The Radialis indicis is also situated between the abductor indicis and adductor pollicis, and runs along the radial side of the index finger, forming its collateral artery. This vessel is frequently a branch of the princeps pollicis.

The Interossea, three or four in number, are branches of the deep palmar arch; they pass forward upon the interossei muscles and inosculate with the digital branches of the superficial arch, opposite the heads of the metacarpal bones.

The Perforantes, three in number, pass directly backwards between the heads of the dorsal interossei muscles, and inosculate with the posterior interosseous arteries.

ULNAR ARTERY.

The Ulnar artery, the other division of the brachial artery, crosses the arm obliquely to the commencement of its middle third; it then runs down the ulnar side of the fore-arm to the wrist, crosses the annular ligament, and forms the superficial palmar arch, which terminates by inosculating with the superficialis vulae.

Relations.—In the upper or oblique portion of its course, it lies upon the brachialis anticus and flexor profundus digitorum; and is covered in by the superficial layer of muscles of the fore-arm and the median nerve. In the second part of its course, it is placed upon the flexor profundus and pronator quadratus, lying between the flexor carpi ulnaris and flexor sublimis digitorum. While crossing the annular ligament it is protected from injury by a strong tendinous arch, thrown over it from the pisiform bone; and in the palm it rests upon the tendons of the flexor sublimis, being covered in by the palmaris
brevis muscle and palmar fascia. It is accompanied in its course by the venae comites, and is in relation with the ulnar nerve for the lower two-thirds of its extent.

Plan of the *relations* of the Ulnar Artery.

  - Carpalis posterior.

- **Hand,**
  - Digitales.

The *Anterior ulnar recurrent* arises immediately below the elbow, and ascends in front of the joint between the pronator radii teres and brachialis anticus, where it inosculates with the anastomotica magna and inferior profunda. The two recurrent arteries frequently arise by a common trunk.

The *Posterior ulnar recurrent*, larger than the preceding, arises immediately below the elbow joint, and passes backwards beneath the origins of the superficial layer of muscles; it then ascends between the two heads of the flexor carpi ulnaris, and beneath the ulnar nerve, and inosculates with the inferior profunda and anastomotica magna.
The Common interosseous artery is a short trunk which arises from the ulnar, opposite the bicipital tuberosity of the radius. It divides into two branches, the anterior and posterior interosseous arteries.

The Anterior interosseous passes down the fore-arm upon the interosseous membrane, between the flexor profundus digitorum and flexor longus pollicis, and, behind the pronator quadratus it pierces that membrane and descends to the back of the wrist, where it inosculates with the posterior carpal branches of the radial and ulnar. It is retained in connection with the interosseous membrane by means of a thin aponeurotic arch.

The anterior interosseous artery sends a branch to the median nerve, which it accompanies into the hand. The median artery is sometimes of large size, and occasionally takes the place of the superficial palmar arch.

The Posterior interosseous artery passes backwards through an opening between the upper part of the interosseous membrane and the oblique ligament, and is distributed to the muscles on the posterior aspect of the fore-arm. It gives off a recurrent branch, which returns upon the elbow between the anconeus, extensor carpi ulnaris and supinator brevis muscles, and anastomoses with the posterior terminal branches of the superior profunda.

The Muscular branches supply the muscles situated along the ulnar border of the fore-arm.

The Carpal branches, anterior and posterior, are distributed to the anterior and posterior aspects of the wrist-joint, where they inosculate with corresponding branches of the radial artery.

The Digital branches are given off from the superficial palmar arch, and are four in number. The first and smallest is distributed to the ulnar side of the little finger. The other three are short trunks, which divide between the heads of the metacarpal bones, and form the collateral branch of the radial side of the little finger, the collateral branches of the ring and middle fingers, and the collateral branch of the ulnar side of the index finger.

The Superficial palmar arch receives the termination of the deep palmar arch from between the abductor minimi digiti and flexor brevis minimi digiti near their origins, and terminates by inosculating with the superficialis volæ upon the ball of the thumb. The communication between the superficial and deep arch is generally described as the communicating branch of the ulnar artery.

The mode of distribution of the arteries to the hand is subject to frequent variety.

BRANCHES OF THE THORACIC AORTA.

 Bronchial,
  Esophageal,
  Intercostal.

The Bronchial arteries are four in number, and vary both in
size and origin. They are distributed to the bronchial glands and tubes, and send branches to the oesophagus, pericardium, and left auricle of the heart. These are the nutritious vessels of the lungs.

The **oesophageal arteries** are numerous small branches; they arise from the anterior part of the aorta, are distributed to the oesophagus, and establish a chain of anastomoses along that tube: the superior inosculate with the bronchial arteries, and with oesophageal branches of the inferior thyroid arteries; and the inferior with similar branches of the phrenic and gastric arteries.

The **intercostal**, or posterior intercostal arteries, arise from the posterior part of the aorta; they are nine in number on each side, the two superior spaces being supplied by the superior intercostal artery, a branch of the subclavian. The right intercostals are longer than the left, on account of the position of the aorta. They ascend somewhat obliquely from their origin, and cross the vertebral column behind the thoracic duct, vena azygos major, and sympathetic nerve, to the intercostal spaces, the left passing beneath the superior intercostal vein, the vena azygos minor and sympathetic. In the intercostal spaces, or rather, upon the external intercostal muscles, each artery gives off a dorsal branch, which passes back between the transverse processes of the vertebrae, lying internally to the middle costo-transverse ligament, and divides into a spinal branch, which supplies the spinal cord and vertebrae, and a muscular branch which is distributed to the muscles and integument of the back. The artery then comes into relation with its vein and nerve, the former being above and the latter below, and divides into two branches which run along the borders of contiguous ribs between the two planes of intercostal muscles, and anastomose with the anterior intercostal arteries, branches of the internal mammary. The branch corresponding with the lower border of each rib is the larger of the two. They are protected from pressure during the action of the intercostal muscles, by little tendinous arches thrown across them and attached by each extremity to the bone.

**Branches of the abdominal aorta.**

Phrenic,

Coeliac axis \{ Gastric,

Hepatic,

Splenic.

Superior mesenteric,

Spermatic,

Inferior mesenteric,

Supra-renal,

Renal,

Lumbar,

Sacra media.
The Phrenic Arteries are given off from the anterior part of the aorta as soon as that trunk has passed through the aortic opening. Passing obliquely outwards upon the under surface of the diaphragm, each artery divides into two branches, an internal branch which runs forwards and inosculates with its fellow of the opposite side in front of the oesophageal opening; and an external branch which proceeds outwards towards the great circumference of the muscle, and sends branches to the supra-renal capsules. The phrenic arteries inosculates with branches of the internal mammary, inferior intercostal, epigastric, oesophageal, gastric, hepatic, and supra-renal arteries. They are not unfrequently derived from the celiac axis, or from one of its divisions, and sometimes they give off the supra-renal arteries.

The Celiac Axis (cauli, ventriculus) is the first single trunk given off from the abdominal aorta. It arises opposite the upper border of the first lumbar vertebra, is about half an inch in length, and divides into three large branches, gastric, hepatic, and splenic.

Relations.—The trunk of the celiac axis has in relation with it, in front the lesser omentum; on the right side the right semilunar ganglion and lobus Spigelii of the liver; on the left side the left semilunar ganglion and cardiac portion of the stomach; and below, the upper border of the pancreas and lesser curve of the stomach. It is completely surrounded by the solar plexus.

The Gastric Artery (coronaria ventriculi), the smallest of the three branches of the celiac axis, ascends between the two layers of the lesser omentum to the cardiac orifice of the stomach, then runs along the lesser curvature to the pylorus, and inosculates with the pyloric branch of the hepatic. It is distributed to the lower extremity of the esophagus and lesser curve of the stomach, and anastomoses with the oesophageal arteries and vasa brevia of the splenic artery.

The Hepatic Artery curves forwards, and ascends along the right border of the lesser omentum to the liver, where it divides into two branches (right and left), which enter the transverse fissure, and are distributed along the portal canals to the right and left lobes.* It is in relation in the right border of the lesser omentum, with the ductus communis choledochus and portal vein, and is surrounded by the hepatic plexus of nerves and numerous lymphatics. There are sometimes two hepatic arteries, in which case one is derived from the superior mesenteric artery.

The Branches of the hepatic artery are, the

Pyloric,
Gastro-duodenalis,  \ Gastro-epiploica dextra,
\ Pancreatico-duodenalis.
Cystic.

* For the mode of distribution of the hepatic artery within the liver, see the "Minute Anatomy" of that organ in the Chapter on the Viscera.

The **Pyloric branch** given off from the hepatic near the pylorus, is distributed to the commencement of the duodenum and to the lesser curve of the stomach, where it inosculates with the gastric artery.

The **Gastro-duodenalis artery** is a short but large trunk, which descends behind the pylorus, and divides into two branches, the gastro-epiploica dextra, and pancreatico-duodenalis. Previously to its division, it gives off some **inferior pyloric** branches to the small end of the stomach.

The **Gastro-epiploica dextra** runs along the great curve of the stomach lying between the two layers of the great omentum, and inosculates at about its middle with the gastro-epiploica sinistra, a branch of the splenic artery. It supplies the great curve of the stomach and the great omentum; hence the derivation of its name.

The **Pancreatico-duodenalis** curves along the fixed border of the duodenum, partly concealed by the attachment of the pancreas, and is distributed to the pancreas and duodenum. It inosculates inferiorly with the first jejunal, and with the pancreatic branches of the superior mesenteric artery.

The **Cystic artery**, generally a branch of the right hepatic, is of small size, and ramifies between the coats of the gall bladder, previously to its distribution to the mucous membrane.

The **Splenic artery**, the largest of the three branches of the cælic axis, passes horizontally to the left along the upper border of the pancreas, and divides into five or six large branches which enter the hilus of the spleen and are distributed to its structure. In its course it is tortuous and serpentine, and frequently makes a complete turn upon itself. It lies in a narrow groove in the upper border of the pancreas, and is accompanied by the splenic vein, and by the splenic plexus of nerves.

The **Branches** of the splenic artery are the —

- Pancreatice parvae,
- Pancreatica magna,
- Vasa brevia,
- Gastro-epiploica sinistra.

The **Pancreatice parvae** are numerous small branches distributed to the pancreas, as the splenic artery runs along its upper border. One of these, larger than the rest, follows the course of the pancreatic duct, and is called **pancreatica magna**.

The **Vasa brevia** are five or six branches of small size which pass from the extremity of the splenic artery and its terminal branches, between the layers of the gastro-splenic omentum, to the great end of the stomach, to which they are distributed, inosculating with branches of the gastric artery and gastro-epiploica sinistra.

The **Gastro-epiploica sinistra** appears to be the continuation of the splenic artery; it passes forwards from left to right, along the great
curve of the stomach, lying between the layers of the great omentum, and inosculates with the gastro-epiploica dextra. It is distributed to the greater curve of the stomach and to the great omentum.

The Superior Mesenteric Artery, the second of the single trunks, and next in size to the celiac axis, arises from the aorta immediately below that vessel, and behind the pancreas. It passes forwards between the pancreas and transverse duodenum, and descends within the layers of the mesentery, to the right iliac fossa, where it terminates.

very much diminished in size. It forms a curve in its course, the convexity being directed towards the left, and the concavity to the right. It is in relation near its commencement with the portal vein: and is accompanied by two veins, and the superior mesenteric plexus of nerves.

The branches from the convexity of the superior mesenteric to the small intestines.
The branches of the superior Mesenteric Artery are—

Vasa intestini tenuis,
Ileo-colica,
Colica dextra,
Colica media.

The Vasa intestini tenuis arise from the convexity of the superior mesenteric artery. They vary from fifteen to twenty in number, and are distributed to the small intestine from the duodenum to the termination of the ileum. In their course between the layers of the mesentery, they form a series of arches by the inosculcation of their larger branches; from these are developed secondary arches, and from the latter a third series of arches, from which the branches arise which are distributed to the coats of the intestine. From the middle branches a fourth and sometimes even a fifth series of arches is produced. By means of these arches a direct communication is established between all the branches given off from the convexity of the superior mesenteric artery; the superior branches moreover supply the pancreas and duodenum, and inosculate with the pancreatico-duodenalis; and the inferior with the ileo-colica.

The Ileo-colic artery is the last branch given off from the concavity of the superior mesenteric. It descends to the right iliac fossa, and divides into branches which communicate and form arches, from which branches are distributed to the termination of the ileum, the caecum, and the commencement of the colon. This artery inosculates on the one hand with the last branches of the vasa intestini tenuis, and on the other with the colica dextra.

The Colica dextra arises from about the middle of the concavity of the superior mesenteric, and divides into branches which form arches, and are distributed to the ascending colon. Its descending branches inosculate with the ileo-colica, and the ascending with the colica media.

The Colica media arises from the upper part of the concavity of the superior mesenteric, and passes forwards between the layers of the transverse mesocolon, where it forms arches, and is distributed to the transverse colon. It inosculates on the right with the colica dextra; and on the left with the colica sinistra, a branch of the inferior mesenteric artery.

The Spermatic arteries are two small vessels which arise from the front of the aorta below the superior mesenteric; from this origin each artery passes obliquely outwards, and accompanies the corresponding ureter along the front of the psoas muscle to the border of the pelvis, where it is in relation with the external iliac artery. It is then directed outwards to the internal abdominal ring, and follows the course of the spermatic cord along the spermatic canal and through the scrotum to the testicle, to which it is distributed. The right spermatic artery
lies in front of the vena cava, and both vessels are accompanied by their corresponding veins and by the spermatic plexuses of nerves.

The cæcum and appendix cæci. 3. The ascending colon. 4. The transverse colon raised upwards. 5. The descending colon. 6. Its sigmoid flexure. 7. The rectum. 8. The aorta. 9. The inferior mesenteric artery. 10. The colica sinistra, insuscultating with, 11, the colica media, a branch of the superior mesenteric artery. 12, 12. Sigmoid branches. 13. The superior haemorrhoidal artery. 14. The pancreas. 15. The descending portion of the duodenum.

Fig. 125.*
The spermatic arteries in the female descend into the pelvis and pass between the two layers of the broad ligaments of the uterus, to be distributed to the ovaries, Fallopian tubes, and round ligaments; along the latter they are continued to the inguinal canal and labium at each side.

They inosculate with the uterine arteries.

The **Inferior mesenteric artery**, smaller than the superior, arises from the abdominal aorta, about two inches below the origin of that vessel, and descends between the layers of the left mesocolon, to the left iliac fossa, where it divides into three branches:

- Colica sinistra,
- Sigmoideæ,
- Superior hæmorrhoidal.

The *Colica sinistra* is distributed to the descending colon, and ascends to inosculate with the colica media. This is the largest arterial inosulation in the body.

The *Sigmoideæ* are several large branches which are distributed to the sigmoid flexure of the descending colon. They form arches, and inosculate above with the colica sinistra, and below with the superior haemorrhoidal artery.

The *Superior hæmorrhoidal* artery is the continuation of the inferior mesenteric. It crosses the ureter and common iliac artery of the left side, and descends between the two layers of the meso-rectum as far as the middle of the rectum to which it is distributed, anastomosing with the middle and external haemorrhoidal arteries.

The **Supra-renal** are two small vessels which arise from the aorta immediately above the renal arteries, and are distributed to the supra-renal capsules. They are sometimes branches of the phrenic or of the renal arteries.

The **Renal arteries** (emulgent) are two large trunks given off from the sides of the aorta immediately below the superior mesenteric artery; the right is longer than the left on account of the position of the aorta, and passes behind the vena cava to the kidney of that side. The left is somewhat higher than the right. They divide into several large branches previously to entering the kidney, and ramify very minutely in its vascular portion. The renal arteries supply several small branches to the supra-renal capsules.

The **Lumbar arteries** correspond with the intercostals in the chest; they are four or five in number on each side, and curve around the bodies of the lumbar vertebrae beneath the psoas muscles, and divide into two branches; one of which passes backwards between the transverse processes, and is distributed to the vertebrae and spinal cord.
and to the muscles of the back, whilst the other takes its course behind the quadratus lumborum muscle and supplies the abdominal muscles. The first lumbar artery runs along the lower border of the last rib, and the last along the crest of the ilium. In passing between the psoas muscles and the vertebrae, they are protected by a series of tendinous arches, which defend them and the communicating branches of the sympathetic nerve from pressure during the action of the muscle.

The Sacra media arises from the posterior part of the aorta at its bifurcation, and descends along the middle of the anterior surface of the sacrum to the first piece of the coccyx where it terminates by inosculating with the lateral sacral arteries. It distributes branches to the rectum and anterior sacral nerves, and inosculates on either side with the lateral sacral arteries.

Varieties in the Branches of the abdominal Aorta.—The phrenic arteries are very rarely both derived from the aorta. One or both may be branches of the celiac axis; one may proceed from the gastric artery, from the renal, or from the upper lumbar artery. There are occasionally three or more phrenic arteries. The celiac axis is very variable in length, and gives off its branches irregularly. There are sometimes two or even three hepatic arteries, one of which may be derived from the gastric or even from the superior mesenteric. The colica media is sometimes derived from the hepatic artery. The spermatic arteries are very variable both in origin and number. The right spermatic may be a branch of the renal artery, and the left a branch of the inferior mesenteric. The supra-renal arteries may be derived from the phrenic or renal arteries. The renal arteries present several varieties in number; there may be three or even four arteries on one side, and one only on the other. When there are several renal arteries on one side, one may arise from the common iliac artery, from the front of the aorta near its lower part, or from the internal iliac.

Common Iliac Arteries.

The abdominal aorta divides opposite the fourth lumbar vertebra into the two common iliac arteries. Sometimes the bifurcation takes place as high as the third, and occasionally as low as the fifth lumbar vertebra. The common iliac arteries are about two inches and a half in length; they diverge from the termination of the aorta, and pass downwards and outwards on each side to the margin of the pelvis opposite the sacro-iliac symphysis, where they divide into the internal and external iliac arteries. In old persons the common iliac arteries are more or less dilated and curved in their course.

The Right common iliac is somewhat longer than the left, and forms a more obtuse angle with the termination of the aorta; the angle of bifurcation is greater in the female than in the male.

Relations.—The relations of the two arteries are different on the
two sides of the body. The right common iliac is in relation in front with the peritoneum, and is crossed at its bifurcation by the ureter. It is in relation posteriorly with the two common iliac veins, and externally with the psoas magnus. The left is in relation in front with the peritoneum, and is crossed by the rectum and superior hæmorrhoidal artery, and at its bifurcation by the ureter. It is in relation behind with the left common iliac vein, and externally with the psoas magnus.

**INTERNAL Iliac Artery.**

The Internal Iliac Artery is a short trunk, varying in length from an inch to two inches. It descends obliquely to a point opposite the upper margin of the great sacro-ischiatic foramen, where it divides into an anterior and a posterior trunk.

---

*Fig. 126.*

* The distribution and branches of the iliac arteries. 1. The aorta. 2. The left common iliac artery. 3. The external iliac. 4. The epigastric artery. 5. The circumflexa illi. 6. The internal iliac artery. 7. Its anterior trunk. 8. Its posterior trunk. 9. The umbilical artery giving off (10) the superior vesical artery. After the origin of this branch, the umbilical artery becomes converted into a fibrous cord—the umbilical ligament. 11. The internal pudic artery passing behind the spine of the ischium (12) and lesser sacro-ischiatic ligament. 13. The middle hæmorrhoidal artery. 14. The ischiatic artery, also passing behind the anterior sacro-ischiatic ligament to escape from the pelvis. 15. Its inferior vesical branch. 16. The ilio-lumbar, the first branch of the posterior trunk (8) ascending to inosculate with the circumflexa illi artery (5) and form an arch along the crest of the ilium. 17. The obturator artery. 18. The lateral sacral. 19. The gluteal artery escaping from the pelvis through the upper part of the great sacro-ischiatic foramen. 20. The sacra media. 21. The right common iliac artery cut short. 22. The femoral artery.
Relations.—This artery rests externally upon the sacral plexus and upon the origin of the pyriformis muscle; posteriorly it is in relation with the internal iliac vein, and anteriorly with the ureter.

Branches.—The branches of the anterior trunk are the—

Umbilical, Ischiatic,
Middle vesical, Internal pudic,
Middle hæmorrhoidal,

And in the female the—

Uterine, Vaginal.

And of the posterior trunk, the—

Ilio-lumbar, Lateral sacral,
Obturator, Gluteal.

The umbilical artery is the commencement of the fibrous cord into which the umbilical artery of the fetus is converted after birth. In after life, the cord remains pervious for a short distance and constitutes the umbilical artery of the adult, from which the superior vesical artery is given off to the fundus and anterior aspect of the bladder. The cord may be traced forwards by the side of the fundus of the bladder to near its apex, whence it ascends by the side of the linea alba and urachus to the umbilicus.

The Middle vesical artery is generally a branch of the umbilical, and sometimes of the internal iliac. It is somewhat larger than the superior vesical, and is distributed to the posterior part of the body of the bladder, the vesiculae seminales, and prostate gland.

The Middle hæmorrhoidal artery is as frequently derived from the ischiatic or internal pudic as from the internal iliac. It is of variable size, and is distributed to the rectum, base of the bladder, vesiculae seminales, and prostate gland; and inosculates with the superior and external hæmorrhoidal arteries.

The Ischiatic artery is the larger of the two terminal branches of the anterior division of the internal iliac. It passes downwards between the posterior border of the levator ani, and the pyriformis, resting upon the sacral plexus of nerves and lying behind the internal pudic artery, to the lower border of the great ischiatic notch, where it escapes from the pelvis below the pyriformis muscle. It then descends in the space between the trochanter major and the tuberosity of the ischium in company with the ischiatic nerves, and divides into branches.

Its branches within the pelvis are hæmorrhoidal which supply the rectum conjointly with the middle hæmorrhoidal and sometimes take the place of that artery, and the inferior vesical which is distributed to the base and neck of the bladder, the vesiculae seminales, and
prostate gland. The branches external to the pelvis, are four in number, namely, coccygeal, inferior gluteal, comes nervi ischiatici, and muscular branches.

The Coccygeal branch pierces the great sacro-ischiatic ligament, and is distributed to the coccygeus and levator ani muscles, and to the integument around the anus and coccyx.

The Inferior gluteal branches supply the gluteus maximus muscle.

The Comes nervi ischiatici is a small but regular branch, which accompanies the great ischiatic nerve to the lower part of the thigh.

The Muscular branches supply the muscles of the posterior part of the hip and thigh, and inosculate with the internal and external circumflex arteries, with the obturator, and with the superior perforating artery.

The Internal pudic artery, the other terminal branch of the anterior trunk of the internal iliac, descends in front of the ischiatic artery to the lower border of the great ischiatic foramen. It emerges from the pelvis through the great sacro-ischiatic foramen below the pyriformis muscle, crosses the spine of the ischium, and re-enters the pelvis through the lesser sacro-ischiatic foramen; it then crosses the internal obturator muscle to the ramus of the ischium, being situated at about an inch from the margin of the tuberosity, and bound down by the obturator fascia; it next ascends the ramus of the ischium, enters between the two layers of the deep perineal fascia lying along the border of the ramus of the os pubis, and at the symphysis pierces the anterior layer of the deep perineal fascia, and very much diminished in size reaches the dorsum of the penis along which it runs, supplying that organ under the name of the dorsalis penis.

Branches.—The branches of the internal pudic artery within the pelvis are several small ramusculæ to the base of the bladder, the vesiculae seminales, and the prostate gland; and hæmorrhoidal branches which supply the middle of the rectum, and frequently take the place of the middle hæmorrhoidal branch of the internal iliac.

The branches, external to the pelvis, are the

External hæmorrhoidal,
Superficialis perinei,
Transversalis perinei,
Arteria bulbosi,
Arteria corporis cavernosi,
Arteria dorsalis penis.

The External hæmorrhoidal arteries are three or four small branches, given off by the internal pudic while behind the tuberosity of the ischium. They are distributed to the anus, and to the muscles, the fascia, and the integument in the anal region of the perineum.

The Superficial perineal artery is given off near the attachment of the crus penis; it pierces the connecting layer of the superficial and
deep perineal fascia, and runs forward across the transversus perinei muscle, and along the groove between the accelerator urinae and erector penis to the septum scroti, upon which it ramifies under the name of arteria septi. It distributes branches to the scrotum, and to the perineum in its course forwards. One of the latter, larger than the rest, crosses the perineum, resting on the transversus perinei muscle, and is named the transversalis perinei.

The Artery of the bulb is given off from the pudic nearly opposite the opening for the transmission of the urethra; it passes almost transversely inwards between the two layers of the deep perineal fascia, and pierces the anterior layer to enter the corpus spongiosum at its bulbous extremity. It is distributed to the corpus spongiosum.

* The arteries of the perineum; on the right side the superficial arteries are seen, and on the left the deep. 1. The penis, consisting of corpus spongiosum and corpus cavernosum. The crus penis on the left side is cut through. 2. The acceleratores urinae muscles, enclosing the bulbous portion of the corpus spongiosum. 3. The erector penis, spread out upon the crus penis of the right side. 4. The anus, surrounded by the sphincter ani muscle. 5. The ramus of the ischium and os pubis. 6. The tuberosity of the ischium. 7. The lesser sacro-ischiatic ligament, attached by its small extremity to the spine of the ischium. 8. The coccyx. 9. The internal pudic artery, crossing the spine of the ischium, and entering the perineum. 10. External haemorrhoidal branches. 11. The superficialis perinei artery, giving off a small branch, transversalis perinei, upon the transversus perinei muscle. 12. The same artery on the left side cut off. 13. The artery of the bulb. 14. The two terminal branches of the internal pudic artery; one is seen entering the divided extremity of the crus penis, the artery of the corpus cavernosum; the other, the dorsalis penis, ascends upon the dorsum of the organ.
The Artery of the corpus cavernosum pierces the crus penis, and runs forward in the interior of the corpus cavernosum, by the side of the septum pectiniforme. It ramifies in the parenchyma of the venous structure of the corpus cavernosum.

The Dorsal artery of the penis ascends between the two crura and symphysis pubis to the dorsum penis, and runs forward through the suspensory ligament in the groove of the corpus cavernosum to the glans, distributing branches in its course to the body of the organ and to the integument.

The Internal pudic artery in the female is smaller than in the male; its branches, with their distribution, are in principle the same. The superficial perineal artery supplies the analogue of the lateral half of the scrotum, viz. the greater labium. The artery of the bulb supplies the meatus urinarius, and the vestibule; the artery of the corpus cavernosum, the cavernous body of the clitoris, and the arteria dorsalis clitoridis, the dorsum of that organ.

The Uterine and Vaginal arteries of the female are derived either from the internal iliac, or from the umbilical, internal pudic, or ischiatic arteries. The former are very tortuous in their course, and ascend between the layers of the broad ligament, to be distributed to the uterus. The latter ramify upon the exterior of the vagina, and supply its mucous membrane.

Branches of the posterior trunk.

The Ilio-lumbar artery ascends beneath the external iliac vessels and psoas muscle, to the posterior part of the crest of the ilium, where it divides into two branches, a lumbar branch which supplies the psoas and iliacus muscles, and sends a ramuscula through the fifth intervertebral foramen to the spinal cord and its membranes; and an iliac branch which passes along the crest of the ilium distributing branches to the iliacus and abdominal muscles, and inosculating with the lumbar and gluteal arteries, and with the circumflexa ili.

The Obturator artery is exceedingly variable in point of origin; it generally proceeds from the posterior trunk of the internal iliac artery, and passes forwards a little below the brim of the pelvis to the upper border of the obturator foramen. It there escapes from the pelvis through a tendinous arch formed by the obturator membrane, and divides into two branches; an internal branch which curves inwards around the bony margin of the obturator foramen, between the obturator externus muscle and the ramus of the ischium, and distributes branches to the obturator muscles, the pectineus, the adductor muscles, and to the organs of generation, and inosculates with the internal circumflex artery. And an external branch which pursues its course along the outer margin of the obturator foramen to the space between the gemellus inferior and quadratus femoris, where it inosculates with
the ischiatic artery. In its course backwards it anastomoses with the internal circumflex, and sends a branch through the notch in the acetabulum to the hip-joint. Within the pelvis the obturator artery gives off a branch to the iliacus muscle, and a small ramuscula which inosculates with the epigastric artery.

The lateral sacral arteries are generally two in number on each side; superior and inferior. The superior passes inwards to the first sacral foramen and is distributed to the contents of the spinal canal, from which it escapes by the posterior sacral foramen, and supplies the integument on the dorsum of the sacrum. The inferior passes down by the side of the anterior sacral foramina to the coccyx; it first pierces and then rests upon the origin of the pyriformis, and sends branches into the sacral canal to supply the sacral nerves. Both arteries inosculate with each other and with the sacra media.

The gluteal artery is the continuation of the posterior trunk of the internal iliac: it passes backwards between the lumbo-sacral and first lumbar nerve through the upper part of the great sacro-ischiatric foramen, and above the pyriformis muscle, and divides into three branches, superficial, deep superior, and deep inferior.

The superficial branch is directed forwards, between the gluteus maximus and medius, and divides into numerous branches, which are distributed to the upper part of the gluteus maximus and to the integument of the gluteal region.

The deep superior branch passes along the superior curved line of the ilium, between the gluteus medius and minimus to the anterior superior spinous process, where it inosculates with the superficial circumflexa illii and external circumflex artery. There are frequently two arteries which follow this course.

The deep inferior branches are several large arteries which cross the gluteus minimus obliquely to the trochanter major, where they inosculate with branches of the external circumflex artery, and send branches through the gluteus minimus to supply the capsule of the hip-joint.

Varieties in the branches of the internal iliac.—The most important of the varieties occurring among these branches is the origin of the dorsal artery of the penis from the internal iliac or ischiatic. The artery in this case passes forwards by the side of the prostate gland, and through the upper part of the deep perineal fascia. It would be endangered in the operation of lithotomy. The dorsal artery of the penis is sometimes derived from the obturator, and sometimes from one of the external pudic arteries. The artery of the bulb, in its normal course, passes almost transversely inwards to the corpus spongiosum. Occasionally, however, it is so oblique in its direction as to render its division in lithotomy unavoidable. The obturator artery may be very small or altogether wanting, its place being supplied by a branch from the external iliac or epigastric.
EXTERNAL Iliac Artery.

The external iliac artery of each side passes obliquely downwards along the inner border of the psoas muscle, from opposite the sacroiliac symphysis to the femoral arch, where it becomes the femoral artery.

Relations.—It is in relation in front with the spermatic vessels, the peritoneum, and a thin layer of fascia, derived from the iliac fascia, which surrounds the artery and vein. At its commencement it is crossed by the ureter, and near its termination by the crural branch of the genito-crural nerve and the circumflexa ili vein. Externally it lies against the psoas muscle, from which it is separated by the iliac fascia; and posteriorly it is in relation with the external iliac vein, which, at the femoral arch, becomes placed to its inner side. The artery is surrounded throughout the whole of its course by lymphatic vessels and glands.

Branches.—Besides several small branches which supply the glands surrounding the artery, the external iliac gives off two branches, the—

Epigastric,
Circumflexa ili.

The Epigastric artery arises from the external iliac near Poupart's ligament; and passing forwards between the peritoneum and transversalis fascia, ascends obliquely to the border of the sheath of the rectus. It enters the sheath near its lower third, passes upwards behind the rectus muscle, to which it is distributed, and in the substance of that muscle inosculates near the ensiform cartilage with the termination of the internal mammary artery. It lies internally to the internal abdominal ring and immediately above the femoral ring, and is crossed near its origin by the vas deferens in the male, and by the round ligament in the female.

The only branches of the epigastric artery worthy of distinct notice are the Cremasteric, which accompanies the spermatic cord and supplies the cremaster muscle; and the ramusculus which inosculates with the obturator artery.

The Epigastric artery forms a prominence of the peritoneum which divides the iliac fossa into an internal and an external portion; it is from the former that direct inguinal hernia issues, and from the latter, oblique inguinal hernia.

The Circumflexa ili arises from the outer side of the external iliac, nearly opposite the epigastric artery. It ascends obliquely along Poupart's ligament, and curving around the crest of the ilium between the attachments of the internal oblique and transversalis muscle, inosculates with the ilio-lumbar and inferior lumbar artery. Opposite the anterior superior spinous process of the ilium, it gives off a large ascending branch which passes upwards between the internal oblique and transversalis, and divides into numerous branches which supply
the abdominal muscles, and inosculate with the inferior intercostal and with the lumbar arteries.

Varieties in the branches of the external iliac.—The epigastric artery not unfrequently* gives off the obturator, which descends in contact with the external iliac vein, to the obturator foramen. In this situation the artery would lie to the outer side of the femoral ring, and would not be endangered in the operation for dividing the stricture of femoral hernia. But occasionally the obturator passes along the free margin of Gimbernat’s ligament in its course to the obturator foramen, and would completely encircle the neck of the hernial sac; a position in which it could scarcely escape the knife of the operator. In a preparation in my anatomical collection the branch of communication between the epigastric and obturator arteries is very much enlarged, and takes this dangerous course.

FEMORAL ARTERY.

Emerging from beneath Poupart’s ligament, the external iliac artery enters the thigh and becomes the femoral. The femoral artery passes down the inner side of the thigh, from Poupart’s ligament, at a point midway between the anterior superior spinous process of the ilium and the symphysis pubis, to the opening in the adductor magnus, at the junction of the middle with the inferior third of the thigh, where it becomes the popliteal artery.

The femoral artery and vein are enclosed in a strong sheath, femoral or crural canal, which is formed for the greater part of its extent by aponeurotic and areolar tissue, and by a process of fascia sent inwards from the fascia lata. Near Poupart’s ligament this sheath is much larger than the vessels it contains, and is continuous with the fascia transversalis, and iliac fascia. If the sheath be opened at this point, the artery will be seen to be situated in contact with the outer wall of the sheath. The vein lies next the artery, being separated from it by a fibrous septum, and between the vein and the inner wall of the sheath, and divided from the vein by another thin fibrous septum, is a triangular interval, into which the sac is protruded in femoral hernia. This space is occupied in the normal state of the parts by loose areolar tissue, and by lymphatic vessels which pierce the inner wall of the sheath to make their way to a gland, situated in the femoral ring.

Relations.—The upper third of the femoral artery is superficial, being covered only by the integument, inguinal glands, and by the

* The proportion in which high division of the obturator artery from the epigastric occurs, is stated to be one in three. In two hundred and fifty subjects examined by Cloquet with a view to ascertain how frequently the high division took place, he found the obturator arising from the epigastric on both sides one hundred and fifty times; on one side twenty-eight times, and six times it arose from the femoral artery.
* A view of the anterior and inner aspect of the thigh, showing the course and branches of the femoral artery. 1. The lower part of the aponeurosis of the external oblique muscle; its inferior margin is Poupart's ligament. 2. The external abdominal ring. 3, 3. The upper and lower part of the sartorius muscle; its middle portion having been removed. 4. The rectus. 5. The vastus internus. 6. The patella. 7. The iliacus and psoas; the latter being nearest the artery. 8. The pectineus. 9. The adductor longus. 10. The tendinous canal for the femoral artery formed by the adductor magnus, and vastus
superficial and deep fasciae. The lower two-thirds are covered by the sartorius muscle. To its outer side the artery is first in relation with the psoas and iliacus, and then with the vastus internus. Behind it rests upon the inner border of the psoas muscle; it is next separated from the pectineus by the femoral vein, profunda vein and artery, and then lies on the adductor longus to its termination: near the lower border of the adductor longus, it is placed in an aponeurotic canal, formed by an arch of tendinous fibres, thrown from the lower border of the adductor longus and the border of the opening in the adductor magnus, to the side of the vastus internus. To its inner side it is in relation at its upper part with the femoral vein, and lower down with the pectineus, adductor longus, and sartorius.

The immediate relations of the artery are the femoral vein, and two saphenous nerves. The vein at Poupart's ligament lies to the inner side of the artery; but lower down gets altogether behind it, and inclines to its outer side. The short saphenous nerve lies to the outer side, and somewhat upon the sheath for the lower two-thirds of its extent; and the long saphenous nerve is situated within the sheath, and in front of the artery for the same extent.

The superficial circumflexa ili artery taking its course along the line of Poupart's ligament, to the crest of the ilium. 2. The superficial epigastric artery. 16. The two external pudic arteries, superficial and deep. 17. The profunda artery, giving off 18, its external circumflex branch; and lower down the three perforantes. A small bend of the internal circumflex artery (8) is seen behind the inner margin of the femoral, just below the deep external pudic artery. 19. The anastomotica magna, descending to the knee, upon which it ramifies (6).
Branches.—The branches of the Femoral Artery are the —

Superficial circumflexa ili,  
Superficial epigastric,  
Superficial external pudic,  
Deep external pudic,  
\{ \text{External circumflex,}  
\text{Profunda}  
\{ \text{Internal circumflex,}  
\text{Three perforating.}  

Muscular,  
Anastomotica magna.

The \textit{Superficial circumflexa ili} artery arises from the femoral, immediately below Poupart's ligament, pierces the fascia lata, and passes obliquely outwards towards the crest of the ilium. It supplies the integument of the groin, the superficial fascia, and inguinal glands.

The \textit{Superficial epigastric} arises from the femoral, immediately below Poupart's ligament, pierces the fascia lata, and ascends obliquely towards the umbilicus between the two layers of superficial fascia. It distributes branches to the inguinal glands and integument, and inosculates with branches of the deep epigastric and internal mammary artery.

The \textit{Superficial external pudic} arises near the superficial epigastric artery; it pierces the fascia lata, at the saphenous opening, and passes transversely inwards crossing the spermatic cord, to be distributed to the integument of the penis and scrotum in the male, and to the labia in the female.

The \textit{Deep external pudic} arises from the femoral, a little lower down than the preceding; it crosses the femoral vein immediately below the termination of the internal saphenous vein, and piercing the pubic portion of the fascia lata passes beneath that fascia to the inner border of the thigh, where it again pierces the fascia; having become superficial, it is distributed to the integument of the scrotum and perineum.

The \textit{Profunda femoris} arises from the femoral artery at two inches below Poupart's ligament: it passes downwards and backwards and a little outwards, behind the adductor longus muscle, pierces the adductor magnus, and is distributed to the flexor muscles on the posterior part of the thigh.

Relations.—In its course downwards it rests successively upon the pectineus, the conjoined tendon of the psoas and iliacus, adductor brevis, and adductor magnus muscles. To its outer side the tendinous insertion of the vastus internus muscle intervenes between it and the femur; on its inner side it is in relation with the pectineus, adductor brevis and adductor magnus; and in front it is separated from the femoral artery, above by the profunda vein and femoral vein, and below by the adductor longus muscle.

Adductor magnus.

Branches.—The branches of the profunda artery are the external circumflex, internal circumflex, and three perforating arteries.

The External circumflex artery passes obliquely outwards between the divisions of the crural nerve, then between the rectus and crureus muscle, and divides into three branches; ascending, which inosculates with the terminal branches of the gluteal artery; descending, which inosculates with the superior external articular artery; and middle, which continues the original course of the artery around the thigh, and anastomoses with branches of the ischiatic, internal circumflex, and superior perforating artery. It supplies the muscles on the anterior and outer side of the thigh.

The Internal circumflex artery is larger than the external; it winds around the inner side of the neck of the femur, passing between the pectineus and psoas, and along the border of the external obturator muscle, to the space between the quadratus femoris and upper border of the adductor magnus, where it anastomoses with the ischiatic, external circumflex, and superior perforating artery. It supplies the muscles on the upper and inner side of the thigh, anastomosing with the obturator artery, and sends a small branch through the notch in the acetabulum into the hip-joint.

The **Superior perforating** artery passes backwards between the pectineus and adductor brevis, pierces the adductor magnus near the femur, and is distributed to the posterior muscles of the thigh; inosculating freely with the circumflex and ischiatic arteries, and with the branches of the middle perforating artery.

The **Middle perforating** artery pierces the tendons of the adductor brevis and magnus, and is distributed like the superior; inosculating with the superior and inferior perforantes. This branch frequently gives off the nutritious artery of the femur.

The **Inferior perforating** artery is given off below the adductor brevis, and pierces the tendon of the adductor magnus, supplying it and the flexor muscles, and inosculating with the middle perforating
artery above, and with the articular branches of the popliteal below. It is through the medium of these branches that the collateral circulation is maintained in the limb after ligature of the femoral artery.

The *Muscular branches* are given off by the femoral artery throughout the whole of its course. They supply the muscles in immediate proximity with the artery, particularly those of the anterior aspect of the thigh. One of these branches, larger than the rest, arises from the femoral immediately below the origin of the profunda, and passing outwards between the rectus and sartorius divides into branches which are distributed to all the muscles of the anterior aspect of the thigh. This may be named the *superior muscular artery*.

The *Anastomotica magna* arises from the femoral while in the tendinous canal formed by the adductors and vastus internus. It runs along the tendon of the adductor magnus to the inner condyle, and inosculates with the superior internal articular artery: some of its branches are distributed to the vastus internus muscle and to the crureus, and terminate by anastomosing with the branches of the external circumflex and superior external articular artery.

**POPLITEAL ARTERY.**

The popliteal artery commences from the termination of the femoral at the opening in the adductor magnus muscle, and passes obliquely outwards through the middle of the popliteal space to the lower border of the popliteus muscle, where it divides into the anterior and posterior tibial artery.

*Relations.*—In its course downwards it rests first on the femur, then on the posterior ligament of the knee-joint, then on the fascia, covering the popliteus muscle. *Superficially* it is in relation with the semi-membranosus muscle, next with a quantity of fat which separates it from the deep fascia, and near its termination with the gastrocnemius, plantaris, and soleus; superficial and external to it is the popliteal vein, and still more superficial and external, the popliteal nerve. By its *inner side* it is in relation with the semi-membranosus, internal condyle of the femur, and inner head of the gastrocnemius; and by its *outer side* with the biceps, external condyle of the femur, the outer head of the gastrocnemius, the plantaris and the soleus.

Femur, Ligamentum posticum Winslowii, Popliteal fascia.

Branches.—The branches of the popliteal artery are the
Superior external articular, Superior internal articular, Azygos articular, Inferior external articular, Inferior internal articular, Sural.

The Superior articular arteries, external and internal, wind around the femur immediately above the condyles, to the front of the knee-joint, anastomosing with each other, with the external circumflex, the anastomotica magna, the inferior articular, and the recurrent of the anterior tibial. The external passes beneath the tendon of the biceps, and the internal through an arched opening beneath the tendon of the adductor magnus. They supply the knee-joint and the lower part of the femur.

The Azygos articular artery pierces the posterior ligament of the joint, the ligamentum posticum Winslowii, and supplies the synovial membrane in its interior. There are frequently several posterior articular arteries.

The Inferior articular arteries wind around the head of the tibia immediately below the joint, and anastomose with each other, the superior articular arteries, and the recurrent of the anterior tibial. The external passes beneath the two external lateral ligaments of the joint, and the internal beneath the internal lateral ligament. They supply the knee-joint and the heads of the tibia and fibula.

The Sural arteries (sura, the calf) are two large muscular branches, which are distributed to the two heads of the gastrocnemius muscle.

ANTERIOR TIBIAL ARTERY.

The anterior tibial artery passes forwards between the two heads of the tibialis posticus muscle, and through the opening in the upper

The inner belly of the gastrocnemius and the soleus. 8. The annular ligament beneath which the extensor tendons and the anterior tibial artery pass into the dorsum of the foot. 9. The anterior tibial artery. 10. Its recurrent branch inosculating with (2) the inferior articular, and (1) the superior articular arteries,
part of the interosseous membrane, to the anterior tibial region. It then runs down the anterior aspect of the leg to the ankle-joint, where it becomes the dorsalis pedis.

Relations.—In its course downwards it rests upon the interosseous membrane (to which it is connected by a little tendinous arch which is thrown across it), the lower part of the tibia, and the anterior ligament of the joint. In the upper third of its course it is situated between the tibialis anticus and extensor longus digitorum, lower down between the tibialis anticus and extensor proprius pollicis; and just before it reaches the ankle it is crossed by the tendon of the extensor proprius pollicis, and becomes placed between that tendon and the tendons of the extensor longus digitorum. Its immediate relations are the vena comites and the anterior tibial nerve, which latter lies at first to its outer side, and at about the middle of the leg becomes placed superficially to the artery.

Branches.—The branches of the Anterior Tibial Artery are the—

Recurrent,
Muscular,
External malleolar,
Internal malleolar.

The Recurrent branch passes upwards beneath the origin of the tibialis anticus muscle to the front of the knee-joint, upon which it is distributed, anastomosing with the articular arteries.

The Muscular branches are very numerous, they supply the muscles of the anterior tibial region.

The Malleolar arteries are distributed to the ankle-joint; the external passing beneath the tendons of the extensor longus digitorum branches of the popliteal. 11. The internal malleolar artery. 17. The external malleolar insinuating with the anterior peroneal artery 12. 13. The dorsalis pedis artery. 14. The tarsea and metatarsal arteries; the tarsea is nearest the ankle, the metatarsal is seen giving off the interosseæ. 15. The dorsalis hallucis artery. 16. The communicating branch.
and peroneus tertius, inosculates with the anterior peroneal artery and with the branches of the dorsalis pedis; the internal, beneath the tendons of the extensor proprius pollicis and tibialis anticus, inosculates with branches of the posterior tibial and internal plantar artery. They supply branches to the ankle-joint.

The **Dorsalis Pedis Artery** is continued forward along the tibial side of the dorsum of the foot, from the ankle to the base of the metatarsal bone of the great toe, where it divides into two branches, the dorsalis hallucis and communicating.

*Relations.*—The dorsalis pedis is situated along the outer border of the tendon of the extensor proprius pollicis; on its fibular side is the innermost tendon of the extensor longus digitorum, and near its termination it is crossed by the inner tendon of the extensor brevis digitorum. It is accompanied by venæ comites, and has the continuation of the anterior tibial nerve to its outer side.

**Plan of the relations of the Dorsalis Pedis Artery.**

*In Front.*
- Integument,
- Deep fascia,
- Inner tendon of the extensor brevis digitorum.

*Inner Side.*
- Tendon of the extensor proprius pollicis.

*Outer Side.*
- Dorsalis Pedis Artery.
- Tendon of the extensor longus digitorum,

- Bones of the tarsus, with their ligaments.

**Branches.**—The branches of this artery are the—
- Tarsea,
- Metatarsae,—interosseae,
- Dorsalis hallucis,—collateral digital,
- Communicating.

The *Tarsea* arches transversely across the tarsus, beneath the extensor brevis digitorum muscle, and supplies the articulations of the tarsal bones and the outer side of the foot; it anastomoses with the external malleolar, the peroneal arteries, and the external plantar.

The *Metatarsae* forms an arch across the base of the metatarsal bones, and supplies the outer side of the foot, anastomosing with the tarsea and with the external plantar artery. The metatarsae gives off three branches, the *interosseae*, which pass forward upon the dorsal interossei muscles, and divide into two collateral branches for adjoining toes. At their commencement these interosseous branches receive the posterior perforating arteries from the plantar arch, and opposite the heads of the metatarsal bones they are joined by the anterior perforating branches from the digital arteries.
The *Dorsalis hallucis* runs forward upon the first dorsal interosseous muscle, and at the base of the first phalanx divides into two branches, one of which passes inwards beneath the tendon of the extensor proprius pollicis, and is distributed to the inner border of the great toe, while the other bifurcates for the supply of the adjacent sides of the great and second toes.

The *Communicating artery* passes into the sole of the foot between the two heads of the first dorsal interosseous muscle, and inosculates with the termination of the external plantar artery.

Besides the preceding, numerous branches are distributed to the bones and articulations of the foot, particularly along the inner border of the latter.

**POSTERIOR TIBIAL ARTERY.**

The posterior tibial artery passes obliquely downwards along the tibial side of the leg from the lower border of the popliteus muscle to the concavity of the os calcis, where it divides into the internal and external plantar artery.

*Relations.*—In its course downwards it lies first upon the tibialis posticus, next upon the flexor longus digitorum, and then upon the tibia; it is covered in by the intermuscular fascia which separates it above from the soleus, and below from the deep fascia of the leg and the integument. It is accompanied by its vena comites, and by the posterior tibial nerve, which latter lies at first to its outer side, then superficially to it, and again to its outer side.

The Peroneal artery is given off from the posterior tibial at about two inches below the lower border of the popliteus muscle; it is nearly as large as the anterior tibial artery, and passes obliquely outwards to the fibula. It then runs downwards along the inner border of the fibula to its lower third, where it divides into the anterior and posterior peroneal artery.

Relations.—The peroneal artery rests upon the tibialis posticus muscle, and is covered in by the soleus, the intermuscular fascia, and the flexor longus pollicis, having the fibula to its outer side.

</table>

Behind.
Tibialis posticus.

Branches.—The branches of the peroneal artery are muscular to the neighbouring muscles, particularly to the soleus, and the two terminal branches anterior and posterior peroneal.

The Anterior peroneal pierces the interosseous membrane at the lower third of the leg, and is distributed on the front of the outer malleolus, anastomosing with the external malleolar and tarsal artery. This branch is very variable in size.

The Posterior peroneal continues onwards along the posterior aspect of the outer malleolus to the side of the os calcis, to which and to the muscles arising from it, it distributes external calcanean branches. It anastomoses with the anterior peroneal, tarsal, external plantar, and posterior tibial artery.

The Nutritious artery of the tibia arises from the trunk of the tibial, frequently above the origin of the peroneal, and proceeds to the nutritios canal which it traverses obliquely from below upwards.

The Muscular branches of the posterior tibial artery are distributed to the soleus and to the deep muscles on the posterior aspect of the leg. One of these branches is deserving of notice, a recurrent branch, which arises from the posterior tibial above the origin of the peroneal their origin. The two inferior are in relation with the popliteus muscle.

10. The anterior tibial artery passing through the angular interspace between the two heads of the tibialis posticus muscle. 11. The posterior tibial artery. 12. PLANTAR ARTERIES.

artery, pierces the soleus and is distributed upon the inner side of the head of the tibia, anastomosing with the inferior internal articular.

The Internal calcanean branches, three or four in number, proceed from the posterior tibial artery immediately before its division; they are distributed to the inner side of the os calcis, to the integument, and to the muscles which arise from its inner tuberosity, and they anastomose with the external calcanean branches, and with all the neighbouring arteries.

PLANTAR ARTERIES.

The Internal plantar artery proceeds from the bifurcation of the posterior tibial at the inner malleolus and passes along the inner

border of the foot between the abductor pollicis and flexor brevis
digitorum muscles, supplying the inner border of the foot and
great toe.

The External plantar artery, much larger than the internal, passes
obliquely outwards between the first and second layers of the plantar
muscles, to the fifth metatarsal space. It then turns horizontally in-
wards between the second and third layers, to the first metatarsal
space, where it inosculates with the communicating branch from the
dorsalis pedis. The horizontal portion of the artery describes a slight
curve, having the convexity forwards; this is the plantar arch.

Branches.—The branches of the external plantar artery are the—

Muscular,
Articular,
Digital,—anterior perforating,
Posterior perforating.

The Muscular branches are distributed to the muscles in the sole of
the foot.

The Articular branches supply the ligaments of the articulations of
the tarsus, and their synovial membranes.

The Digital branches are four in number:—the first is distributed to
the outer side of the little toe; the three others pass forwards to the
cleft between the toes and divide into collateral branches, which sup-
ply the adjacent sides of the three external toes, and the outer side
of the second. At the bifurcation of the toes, a small branch is sent
upwards from each digital artery, to inosculate with the interosse-
ous branches of the metatarsae; these are the anterior perforating
arteries.

The Posterior perforating are three small branches which pass
upwards between the heads of the three external dorsal interossei
muscles to inosculate with the arch formed by the metatarsae
artery.

Varieties in the Arteries of the lower Extremity.—The femoral
artery occasionally divides at Poupart’s ligament into two branches,
and sometimes into three; the former is an instance of the high
division of the profunda artery; and in a case of the latter kind which
occurred during my dissections, the branches were the profunda, the
superficial femoral, and internal circumflex artery. Dr. Quain, in his
“Elements of Anatomy,” records an instance of a high division of the
femoral artery, in which the two vessels became again united in the
popliteal region. The point of origin of the profunda artery varies
considerably in different subjects, being sometimes nearer to and some-
times farther from Poupart’s ligament, but more frequently the former.
The branches of the popliteal artery are very liable to variety in size;
and in all these cases the compensating principle, so constant in the
vascular system, is strikingly manifested. When the anterior tibial is
of small size, the peroneal is large; and, in place of dividing into two
terminal branches at the lower third of the leg, descends to the lower part of the interosseous membrane, and emerges upon the front of the ankle, to supply the dorsum of the foot: or the posterior tibial and plantar arteries are large, and the external plantar is continued between the heads of the first dorsal interosseous muscle, to be distributed to the dorsal surface of the foot. Sometimes the posterior tibial artery is small and thread-like; and the peroneal, after descending to the ankle, curves inwards to the inner malleolus, and divides into the two plantar arteries. If in this case the posterior tibial be sufficiently large to reach the ankle, it inosculates with the peroneal previously to its division. The internal plantar artery sometimes takes the distribution of the external plantar, which is short and diminutive, and the latter not unfrequently replaces a deficient dorsalis pedis.

The varieties of arteries are interesting in the practical application of a knowledge of their principal forms to surgical operations; in their transcendent anatomy, as illustrating the normal distribution in animals; or in many cases, as diverticula permitted by Nature, to teach her observers two important principles:—first, in respect to herself, that, however in her means she may indulge in change, the end is never overlooked, and a limb is as surely supplied by a leash of arteries, various in their course, as by those which we are pleased to consider normal in distribution; and secondly, with regard to us, that we should ever be keenly alive to what is passing beneath our observation, and ever ready in the most serious operation to deviate from our course and avoid—or give eyes to our knife, that it may see—the concealed dangers which it is our pride to be able to contend with and vanquish.

PULMONARY ARTERY.

The pulmonary artery arises from the left side of the base of the right ventricle in front of the origin of the aorta, and ascends obliquely to the under surface of the arch of the aorta, where it divides into the right and left pulmonary arteries. In its course upwards and backwards it inclines to the left side, crossing the commencement of the aorta, and is connected to the under surface of the arch by a ligamentous cord, the remains of the ductus arteriosus.

Relations.—It is enclosed for one half of its extent by the pericardium, and receives the attachment of the fibrous portion of the pericardium by its upper portion. Behind, it rests against the ascending aorta; on either side is the appendix of the corresponding auricle with a coronary artery; and above, the cardiac ganglion and the remains of the ductus arteriosus.

The Right pulmonary artery passes beneath the arch and behind the ascending aorta, and in the root of the lungs divides into three branches for the three lobes.

The Left pulmonary artery, rather larger than the right, passes in front of the descending aorta, to the root of the left lung to which it
is distributed. These arteries divide and subdivide in the structure of the lungs, and terminate in capillary vessels which form a network around the bronchial cells, and become continuous with the radicles of the pulmonary veins.

**Relations.**—In the root of the right lung examined from above downwards, the pulmonary artery is situated between the bronchus, and pulmonary veins; the former being above, the latter below; while in the left lung the artery is the highest, next the bronchus, and then the veins. On both sides, from before backwards, the artery is situated between the veins and bronchi, the former being in front, and the latter behind.
CHAPTER VI.

OF THE VEINS.

The veins are the vessels which return the blood to the auricles of the heart, after it has been circulated by the arteries through the various tissues of the body. They are much thinner in structure than the arteries, so that when emptied of their blood they become flattened and collapsed. The veins of the systemic circulation convey the dark-coloured and impure or venous blood from the capillary system to the right auricle of the heart, and they are found after death to be more or less distended with that fluid. The veins of the pulmonary circulation resemble the arteries of the systemic circulation in containing during life the pure or arterial blood, which they transmit from the capillaries of the lungs to the left auricle.

The veins commence by minute radicles in the capillaries which are everywhere distributed through the textures of the body, and converge to constitute larger and larger branches, till they terminate in the large trunks which convey the venous blood directly to the heart. In diameter they are larger than the arteries, and like those vessels their combined areas would constitute an imaginary cone, whereof the apex is placed at the heart, and the base at the surface of the body. It follows from this arrangement, that the blood in returning to the heart is passing from a larger into a smaller channel, and therefore that it increases in rapidity during its course.

Veins admit of a threefold division, into superficial, deep, and sinuses.

The Superficial veins return the blood from the integument and superficial structures, and take their course between the layers of the superficial fascia; they then pierce the deep fascia in the most convenient and protected situations, and terminate in the deep veins. They are unaccompanied by arteries, and are the vessels usually selected for venesection.

The Deep veins are situated among the deeper structures of the body and generally in relation with the arteries; in the limbs they are enclosed in the same sheath with those vessels, and they return the venous blood from the capillaries of the deep tissues. In company with all the smaller, and also with the secondary arteries, as the brachial, radial, and ulnar in the upper, and the tibial and peroneal in the lower extremity, there are two veins, placed one on each side of
the artery, and named *vena comites*. The larger arteries, as the axillary, subclavian, carotid, popliteal, femoral, &c., are accompanied by a single venous trunk. *Sinuses* differ from veins in their structure; and also in their mode of distribution, being confined to especial organs and situated within their substance. The principal venous sinuses are those of the dura mater, the diplotê, the cancellous structure of bones, and the uterus.

The communications between veins are even more frequent than those of arteries, and they take place between the larger as well as among the smaller vessels; the *vena comites* communicate with each other very frequently in their course, by means of short transverse branches which pass across from one to the other. These communications are strikingly exhibited in the frequent inosculations of the spinal veins, and in the various venous plexuses, as the spermatic plexus, vesical plexus, &c. The office of these inosculations is very apparent, as tending to obviate the obstructions to which the veins are particularly liable from the thinness of their coats, and from their inability to overcome much impediment by the force of their current.

Veins, like arteries, are composed of three coats, external or cellulo-fibrous, middle or fibrous, and internal or serous. The *external coat* is firm and strong, and resembles that of arteries. The *middle coat* consists of two layers, an outer layer of contractile fibrous tissue disposed in a circular direction around the vessel, and an inner layer of organic muscular fibres arranged longitudinally. This latter resembles the inner layer of the middle coat of arteries, but is somewhat thicker, and is not unfrequently hypertrophied. The *internal coat*, as in arteries, consists of a striated or fenestrated layer, and a layer of epithelium; it is continuous with the internal coat of arteries through the medium of the lining membrane of the heart on the one hand, and through the capillary vessels on the other. The differences in structure, therefore, between arteries and veins relate to the difference of thickness of their component layers, and to the absence of the elastic coat in the latter. Moreover, another difference occurs in the presence of valves. The valves of veins are composed of a thin layer of fibrous membrane, lined upon its two surfaces by epithelium. The segments or flaps of the valves of veins are semilunar in form and arranged in pairs, one upon either side of the vessel; in some instances there is but a single flap, which has a spiral direction, and occasionally there are three. The free border of the valvular flaps is concave, and directed forwards, so that while the current of blood is permitted to flow freely towards the heart, the valves are distended and the current intercepted if the stream becomes retrograde in its course. Upon the cardiac side of each valve the vein is expanded into two pouches (*sinuses*), corresponding with the flaps of the valves, which give to the distended or injected vein a knotted appearance. The valves are most numerous in the veins of the extremities, particularly in the deeper veins, and they are generally absent in the very small veins, and in the veins of the viscera, as in the portal and cere-
bral veins: they are also absent in the large trunks, as in the venæ cavae, venæ azygos, innominateæ, and iliac veins.

Sinuses are venous channels, excavated in the structure of an organ, and lined by the internal coat of the veins; of this structure are the sinuses of the dura mater, whose external covering is the fibrous tissue of the membrane, and the internal, the serous layer of the veins. The external investment of the sinuses of the uterus is the tissue of that organ; and that of the bones, the lining membrane of the cells and canals.

Veins, like arteries, are supplied with nutritious vessels, the vasa vasorum; and it is to be presumed that nervous filaments are distributed in their coats.

I shall describe the veins according to the primary division of the body; taking first, those of the head and neck; next, those of the upper extremity; then, those of the lower extremity; and lastly, the veins of the trunk.

**VEINS OF THE HEAD AND NECK.**

The veins of the head and neck may be arranged into three groups, viz. 1. Veins of the exterior of the head. 2. Veins of the diploë and interior of the cranium. 3. Veins of the neck.

The veins of the exterior of the head are the—

Facial,
Internal maxillary,
Temporal,
Temporo-maxillary,
Posterior auricular,
Occipital.

The Facial vein commences upon the anterior part of the skull in a venous plexus, formed by the communications of the branches of the temporal, and descends along the middle line of the forehead, under the name of frontal vein, to the root of the nose, where it is connected with its fellow of the opposite side by a communicating trunk which constitutes the nasal arch. There are usually two frontal veins which communicate by a transverse inosculature; but sometimes the vein is single and bifurcates at the root of the nose, into the two angular veins. From the nasal arch, the frontal is continued downwards by the side of the root of the nose, under the name of the angular vein; it then passes beneath the zygomatic muscles and becomes the facial vein, and descends along the anterior border of the masseter muscle, crossing the body of the lower jaw, by the side of the facial artery, to the submaxillary gland, and from thence to the internal jugular vein in which it terminates.

The branches which the facial vein receives in its course are, the
supra-orbital, which joins the frontal vein; the dorsal veins of the nose which terminate in the nasal arch; the opthalmic, which communicates with the angular vein; the palpebral and nasal, which open into the angular vein; a considerable trunk, the alveolar, which returns the blood from the spheno-maxillary fossa, from the infra-orbital, palatine, vidian, and sphenopalatine veins, and joins the facial beneath the zygomatic process of the superior maxillary bone, and the veins corresponding with the branches of the facial artery.

The Internal maxillary vein receives the branches from the zygomatic and pterygoid fossae; these are so numerous and communicate so freely as to constitute a pterygoid plexus. Passing backwards behind the neck of the lower jaw, the internal maxillary joins with the temporal vein, and the common trunk resulting from this union constitutes the temporo-massary vein.

The Temporal vein commences on the vertex of the head by a plexiform network which is continuous with the frontal, the temporal, auricular and occipital veins. The ramifications of this plexus form an anterior and a posterior branch which unite immediately above the zygoma; the trunk is here joined by another large vein, the middle temporal, which collects the blood from the temporal muscle, and around the outer segment of the orbit, and pierces the temporal fascia near the root of the zygoma. The temporal vein then descends between the meatus auditorius externus and the condyle of the lower jaw, and unites with the internal maxillary vein, to form the temporo-massary.

The Temporo-maxillary vein formed by the union of the temporal and internal maxillary, passes downwards in the substance of the parotid gland to its lower border, where it becomes the external jugular vein. It receives in its course the anterior auricular, masseteric, transverse facial, and parotid veins, and near its termination is joined by the posterior auricular vein.

The Posterior auricular vein communicates with the plexus upon the vertex of the head, and descends behind the ear to the temporomassary vein, immediately before that vessel merges in the external jugular. It receives in its course the veins from the external ear and the stylo-massary vein.

The Occipital vein commencing posteriorly in the plexus of the vertex of the head, follows the direction of the occipital artery, and passing deeply beneath the muscles of the back part of the neck, terminates in the internal jugular vein. This vein communicates with the lateral sinus by means of a large branch which passes through the mastoid foramen, the mastoid vein.

VEINS OF THE DIPLOE.

The diploë of the bones of the head is furnished in the adult with irregular sinuses, which are formed by a continuation of the internal coat of the veins into the osseous canals in which they are lodged. At
the middle period of life these sinuses are confined to the particular bones; but in old age, after the ossification of the sutures, they may be traced from one bone to the next. They receive their blood from the capillaries supplying the cellular structure of the dipoë, and terminate externally in the veins of the pericranium, and internally in the veins and sinuses of the dura mater. These veins are separated from the bony walls of the canals by a thin layer of medulla.

**Cerebral and Cerebellar Veins.**

The cerebral veins are remarkable for the absence of valves, and for the extreme tenuity of their coats. They may be arranged into the superficial, and deep or ventricular veins.

The *Superficial cerebral veins* are situated upon the surface of the hemispheres, lying in the grooves formed by the convexities of the convolutions. They are named from the position which they may chance to occupy upon the surface of this organ, either superior or inferior, internal or external, anterior or posterior.

The *Superior cerebral veins*, seven or eight in number on each side, pass obliquely forwards, and terminate in the superior longitudinal sinus, in the opposite direction to the course of the stream of blood in the sinus.

The *Deep or Ventricular veins* commence within the lateral ventricles by the veins of the corpora striata and those of the choroid plexus, which unite to form the two vena Galeni.

The *Vena Galeni* pass backwards in the structure of the velum interpositum; and escaping through the fissure of Bichât, terminate in the straight sinus.

The *Cerebellar veins* are disposed, like those of the cerebrum, on the surface of the lobes of the cerebellum; they are situated some upon the superior, and some upon the inferior surface, while others occupy the borders of the organ. They terminate in the lateral and petrosal sinuses.

**Sinuses of the Dura Mater.**

The sinuses of the dura mater are irregular channels, formed by the splitting of the layers of that membrane, and lined upon their inner surface by a continuation of the internal coat of the veins. They may be divided into two groups:—1. Those situated at the upper and back part of the skull. 2. The sinuses at the base of the skull. The former are, the

Superior longitudinal sinus,
Inferior longitudinal sinus,
Straight sinuses,
Occipital sinuses,
Lateral sinuses.
The Superior longitudinal sinus is situated in the attached margin of the falx cerebri, and extends along the middle line of the arch of the skull, from the foramen caecum in the frontal, to the inner tuberosity of the occipital bone, where it divides into the two lateral sinuses. It is triangular in form, is small in front, and increases gradually in size as it passes backwards; it receives the superior cerebral veins which open into it obliquely, numerous small veins from the diploë, and near the posterior extremity of the sagittal suture the parietal veins, from the pericranium and scalp. Examined in its interior, it presents numerous transverse fibrous bands (trabeculae) the chordæ Willisii, which are stretched across its inferior angle; and some small white granular masses, the glandulae Pacchioni; the oblique openings of the cerebral veins, with their valve-like margin, are also seen upon the walls of the sinus.

The termination of the superior longitudinal sinus in the two lateral sinuses forms a considerable dilatation, into which the straight sinus opens from the front, and the occipital sinuses from below. This dilatation corresponds with the jugular fossae.

* The sinuses of the upper and back part of the skull. 1. The superior longitudinal sinus. 2. The cerebral veins opening into the sinus from behind forwards. 3. The falx cerebri. 4. The inferior longitudinal sinus. 5. The straight or fourth sinus. 6. The venæ Galeni. 7. The torcular Herophili. 8. The two lateral sinuses, with the occipital sinuses between them. 9. The termination of the inferior petrosal sinus of one side. 10. The dilatations corresponding with the jugular fossæ. 11. The internal jugular veins.
tation is named the *torcular Herophili,* and is the point of communication of six sinuses, the superior longitudinal, two lateral, two occipital and the straight.

The *Inferior longitudinal sinus* is situated in the free margin of the falx cerebri; it is cylindrical in form, and extends from near the crista galli to the anterior border of the tentorium, where it terminates in the straight sinus. It receives in its course several veins from the falx.

The *Straight or fourth sinus* is the sinus of the tentorium; it is situated at the line of union of the falx with the tentorium; is prismatic in form, and extends across the tentorium, from the termination of the inferior longitudinal sinus to the torcular Herophili. It receives the venæ Galeni, the cerebral veins from the inferior part of the posterior lobes, and the superior cerebellar veins.

The *Occipital sinuses* are two canals of small size, situated in the attached border of the falx cerebelli; they commence by several small veins around the foramen magnum, and terminate by separate openings in the torcular Herophili. They not unfrequently communicate with the termination of the lateral sinuses.

The *Lateral sinuses,* commencing at the torcular Herophili, pass horizontally outwards, in the attached margin of the tentorium, and then curve downwards and inwards along the base of the petrous portion of the temporal bone, at each side, to the foramina lacera posterioria, where they terminate in the internal jugular veins. Each sinus rests in its course upon the transverse groove of the occipital bone, posterior inferior angle of the parietal, mastoid portion of the temporal, and again on the occipital bone. They receive the cerebral veins from the inferior surface of the posterior lobes, the inferior cerebellar veins, the superior petrosal sinuses, the mastoid, and posterior condylid veins, and at their termination, the inferior petrosal sinuses. These sinuses are often unequal in size, the right being larger than the left.

The sinuses of the base of the skull are the—

Cavernous,
Inferior petrosal,
Circular,
Superior petrosal,
Transverse.

The *Cavernous sinuses* are named from presenting a structure similar to that of the corpus cavernosum penis. They are situated on each side of the sella turcica, receiving, anteriorly, the ophthalmic veins through the sphenoidal fissures, and terminating posteriorly in the inferior petrosal sinuses. In the internal wall of each cavernous sinus is

* Torcular (a press), from a supposition entertained by the older anatomists that the columns of blood, coming in different directions, compressed each other at this point.
the internal carotid artery, accompanied by several filaments of the carotid plexus, and crossed by the sixth nerve; and, in its external wall, the third, fourth, and ophthalmic nerves. These structures are separated from the blood flowing through the sinus, by the tubular lining membrane. The cerebral veins from the under surface of the anterior lobes, open into the cavernous sinuses. They communicate by means of the ophthalmic with the facial veins, by the circular sinus with each other, and by the superior petrosal with the lateral sinuses.

The *Inferior petrosal sinuses* are the continuations of the cavernous sinuses backwards along the lower border of the petrous portion of the temporal bone at each side of the base of the skull, to the foramina lacera posteriores, where they terminate with the lateral sinuses in the commencement of the internal jugular veins.

* The sinuses of the base of the skull. 1. The ophthalmic veins. 2. The cavernous sinus of one side. 3. The circular sinus; the figure occupies the position of the pituitary gland in the sella turcica. 4. The inferior petrosal sinus. 5. The transverse or anterior occipital sinus. 6. The superior petrosal sinus. 7. The internal jugular vein. 8. The foramen magnum. 9. The occipital sinuses. 10. The torcular Herophili. 11, 11. The lateral sinuses.
The Circular sinus (sinus of Ridley) is situated in the sella turcica, surrounding the pituitary gland, and communicating on each side with the cavernous sinus. The posterior segment is larger than the anterior.

The Superior petrosal sinuses pass obliquely backwards along the attached border of the tentorium, on the upper margin of the petrous portion of the temporal bone, and establish a communication between the cavernous and lateral sinus at each side. They receive one or two cerebral veins from the inferior part of the middle lobes, and a cerebellar vein from the anterior border of the cerebellum. Near the extremity of the petrous bone these sinuses cross the oval aperture which transmits the fifth nerve.

The Transverse sinus (basilar, anterior occipital) passes transversely across the basilar process of the occipital bone, forming a communication between the two inferior petrosal sinuses. Sometimes there are two sinuses in this situation.

VEINS OF THE NECK.

The veins of the neck which return the blood from the head are the—

External jugular,
Anterior jugular,
Internal jugular,
Vertebral.

The External jugular vein is formed by the union of the posterior auricular vein with the temporo-maxillary, and commences at the lower border of the parotid gland, in front of the sterno-mastoid muscle. It descends the neck in the direction of a line drawn from the angle of the lower jaw to the middle of the clavicle, crosses the sterno-mastoid, and terminates near the posterior and inferior attachment of that muscle in the subclavian vein. In its course downwards it lies upon the anterior lamella of the deep cervical fascia, which separates it from the sterno-mastoid muscle, and is covered in by the platysma myoides and superficial fascia. At the root of the neck it pierces the deep cervical fascia; it is accompanied, for the upper half of its course, by the auricularis magnus nerve. The branches which it receives are the occipital cutaneous and posterior cervical cutaneous, and, near its termination, the supra and posterior scapular.

The external jugular vein is very variable in size, and is occasionally replaced by two veins. In the parotid gland it receives a large communicating branch from the internal jugular vein.

The Anterior jugular vein is a trunk of variable size, which collects the blood from the integument and superficial structures on the fore part of the neck. It passes downwards along the anterior border of the sterno-mastoid muscle, and opens into the subclavian vein, near the termination of the external jugular. The two veins communicate
with each other, with the external, and with the internal jugular vein.

The Internal jugular vein, formed by the convergence of the lateral and inferior petrosal sinus, commences at the foramen lacerum posterior on each side of the base of the skull, and descends the side of the neck, lying, in the first instance, to the outer side of the internal carotid, and then upon the outer side of the common carotid artery to the root of the neck, where it unites with the subclavian, and constitutes the vena innominata. At its commencement, the internal jugular vein is posterior and external to the internal carotid artery, and the eighth and ninth pairs of nerves; lower down, the vein and artery are on the same plane, the glosso-pharyngeal and hypoglossal nerves passing forwards between them, the pneumogastric being between and behind in the same sheath, and the nervus accessorius crossing obliquely behind the vein.

The Branches which the internal jugular receives in its course are, the facial, the lingual, the inferior pharyngeal, the occipital, and the superior and inferior thyroid veins.

The Vertebral vein descends by the side of the vertebral artery in the canal formed by the foramina in the transverse processes of the cervical vertebrae, and terminates at the root of the neck in the commencement of the vena innominata. In the lower part of the vertebral canal it frequently divides into two branches, one of which advances forwards, while the other passes through the foramen in the transverse process of the seventh cervical vertebra, before opening into the vena innominata.

The Branches which it receives in its course are the posterior condylar vein, muscular branches, the cervical meningo-rachidian veins, and, near its termination, the superficial and deep cervical veins.

The Inferior thyroid veins, two, and frequently more in number, are situated one on each side of the trachea, and receive the venous blood from the thyroid gland. They communicate with each other and with the superior thyroid veins, and form a plexus upon the front of the trachea. The right vein terminates in the right vena innominata, just at its union with the superior cava, and the left in the left vena innominata.

VEINS OF THE UPPER EXTREMITY.

The veins of the upper extremity are the deep and superficial. The deep veins accompany the branches and trunks of the arteries, and constitute their venæ comites. The venæ comites of the radial and ulnar arteries are enclosed in the same sheath with those vessels, and terminate at the bend of the elbow in the brachial veins. The brachial venæ comites are situated one on each side of the artery, and open into the axillary vein; the axillary becomes the subclavian, and the subclavian unites with the internal jugular to form the vena innominata.
The **Superficial veins** of the fore-arm are the—

![Diagram of veins](image)

**Anterior ulnar vein,**
**Posterior ulnar vein,**
**Basilic vein,**
**Radial vein,**
**Cephalic vein,**
**Median vein,**
**Median basilic,**
**Median cephalic.**

The **Anterior ulnar vein** collects the venous blood from the inner border of the hand, and from the vein of the little-finger, *vena salivatella*, and ascends the inner side of the fore-arm to the bend of the elbow, where it becomes the basilic vein.

The **Posterior ulnar vein**, irregular in size, and frequently absent, commences upon the inner border and posterior aspect of the hand, and ascending the fore-arm terminates in front of the inner condyle, in the anterior ulnar vein.

The **Basilic vein** (*βασιλική*, royal, or principal) ascends from the common ulnar vein formed by the two preceding, along the inner side of the upper arm, and near its middle pierces the fascia; it then passes upwards to the axilla, and becomes the axillary vein.

The **Radial vein** commences in the large vein of the thumb, on the outer and posterior aspect of the hand, and ascends along the outer border of the fore-arm to the bend of the elbow, where it becomes the cephalic vein.

The **Cephalic vein** (*χεφαλική* the head) ascends along the outer side

* The veins of the fore-arm and bend of the elbow. 1. The radial vein. 2. The cephalic vein. 3. The anterior ulnar vein. 4. The posterior ulnar vein. 5. The trunk formed by their union. 6. The basilic vein, piercing the deep fascia at 7. 9. A communicating branch between the deep veins of the fore-arm and the upper part of the median vein. 10. The median cephalic vein. 11. The median basilic. 12. A slight convexity of the deep fascia, formed by the brachial artery. 13. The process of fascia, derived from the tendon of the biceps, and separating the median basilic vein from the brachial artery. 14. The external cutaneous nerve, piercing the deep fascia, and dividing into two branches, which pass behind the median cephalic vein. 15. The internal cutaneous nerve, dividing into branches, which pass in front of the median basilic vein. 16. The intercosto-humeral cutaneous nerve. 17. The spiral cutaneous nerve, a branch of the musculo-spiral.
of the arm to its upper third; it then enters the groove between the pectoralis major and deltoid muscles, where it is in relation with the descending branch of the thoracico-acromialis artery, and terminates beneath the clavicle in the subclavian vein. A large communicating branch sometimes crosses the clavicle between the external jugular and this vein, which gives it the appearance of being derived directly from the head—hence its appellation.

The *Median vein* is intermediate between the anterior ulnar and radial vein; it collects the blood from the anterior aspect of the forearm, communicating with the two preceding. At the bend of the elbow it receives a branch from the deep veins, and divides into two branches, the median cephalic and median basilic.

The *Median cephalic vein*, generally the smaller of the two, passes obliquely outwards, in the groove between the biceps and supinator longus, to join the cephalic vein. The branches of the external cutaneous nerve pass behind it.

The *Median basilic vein* passes obliquely inwards, in the groove between the biceps and pronator radii teres, and terminates in the basilic vein. This vein is crossed by one or two filaments of the internal cutaneous nerve, and is separated from the brachial artery by the aponeurotic slip given off by the tendon of the biceps.

**AXILLARY VEIN.**

The axillary vein is formed by the union of the *venae comites* of the brachial artery with the basilic vein. It lies in front of the artery, and receives numerous branches from the collateral veins of the branches of the axillary artery; and, at the lower border of the first rib, becomes the subclavian vein.

**SUBCLAVIAN VEIN.**

The subclavian vein crosses over the first rib and beneath the clavicle, and unites with the internal jugular vein to form the vena innominata. It lies at first in front of the subclavian artery, and then in front of the scalenus anticus, which separates it from that vessel. The phrenic and pneumogastric nerves pass between the artery and vein. The veins opening into the subclavian are the cephalic below the clavicle, and the external and anterior jugulars above; occasionally some small veins from the neighbouring parts also terminate in it.

**VEINS OF THE LOWER EXTREMITY.**

The veins of the lower extremity are the deep and superficial. The *deep veins* accompany the branches of the arteries in pairs, and form the *venae comites* of the anterior and posterior tibial and peroneal arteries. These veins unite in the popliteal region to form a single vein of large size, the popliteal, which successively becomes in its course the femoral and the external iliac vein.
POPLITEAL VEIN.

The popliteal vein ascends through the popliteal region, lying, in the first instance, directly upon the artery, and then getting somewhat to its outer side. It receives several muscular and articular branches, and the external saphenous vein. The valves in this vein are four or five in number.

FEMORAL VEIN.

The femoral vein, passing through the opening in the adductor magnus muscle, ascends the thigh in the sheath of the femoral artery, and entering the pelvis beneath Poupart's ligament, becomes the external iliac vein. In the lower part of its course it is situated upon the outer side of the artery; it then becomes placed behind that vessel, and, at Poupart's ligament, lies to its inner side. It receives the muscular veins, and the profunda, and, through the saphenous opening, the internal saphenous vein. The valves in this vein are four or five in number.

The Profunda vein is formed by the convergence of the numerous small veins which accompany the branches of the artery; it is a vein of large size, lying in front of the profunda artery, and terminates in the femoral at about an inch and a half below Poupart's ligament.

The Superficial veins are the external or short, and the internal or long saphenous.

The External saphenous vein collects the blood from the outer side of the foot and leg. It passes behind the outer ankle, ascends along the posterior aspect of the leg, lying in the groove between the two bellies of the gastrocnemius muscle, and pierces the deep fascia in the popliteal region to join the popliteal vein. It receives several cutaneous branches in the popliteal region before passing through the deep fascia, and is accompanied in its course by the external saphenous nerve.

The Internal saphenous vein commences upon the dorsum and inner side of the foot. It ascends in front of the inner ankle, and along the inner side of the leg; it then passes behind the inner condyle of the femur and along the inner side of the thigh to the saphenous opening, where it pierces the sheath of the femoral vessels, and terminates in the femoral vein, at about one inch and a half below Poupart's ligament.

It receives in its course the cutaneous veins of the leg and thigh, and communicates freely with the deep veins. At the saphenous opening it is joined by the superficial epigastric und circumflexa ili veins, and by the external pudic. The situation of this vein in the thigh is not unfrequently occupied by two or even three trunks of nearly equal size.
VEINS OF THE TRUNK.

The veins of the trunk may be divided into 1. The superior vena cava, with its formative branches. 2. The inferior vena cava, with its formative branches. 3. The azygos veins. 4. The vertebral and spinal veins. 5. The cardiac veins. 6. The portal vein. 7. The pulmonary veins.

SUPERIOR VENA CAVA, WITH ITS FORMATIVE BRANCHES.

Venae Innominateae.

The Venae Innominateae are two large trunks, formed by the union of the internal jugular and subclavian vein, at each side of the root of the neck.

The Right vena innominata, about an inch and a quarter in length, lies superficially and externally to the arteria innominata, and descends almost vertically to unite with its fellow of the opposite side in the formation of the superior cava. At the junction of the jugular and subclavian veins it receives from behind the ductus lymphaticus dexter, and lower down it has opening into it the right vertebral, right internal mammary and right inferior thyroid vein.

The Left vena innominata, considerably longer than the right, extends almost horizontally across the roots of the three arteries arising from the arch of the aorta, to the right side of the mediastinum, where it unites with the right vena innominata, to constitute the superior cava.

It is in relation in front with the left sterno-clavicular articulation and the first piece of the sternum. At its commencement it receives the thoracic duct which opens into it from behind, and in its course is joined by the left vertebral, left inferior thyroid, left mammary, and by the superior intercostal vein. It also receives some small veins from the mediastinum and thymus gland. There are no valves in the venae innominatae.

SUPERIOR VENA CAVA.

The superior cava is a short trunk about three inches in length, formed by the junction of the two venae innominatae. It descends perpendicularly on the right side of the mediastinum, and entering the pericardium terminates in the upper part of the right auricle.

It is in relation in front with the thoracic fascia, which separates it from the thymus gland, and with the pericardium; behind with the right pulmonary artery, and right superior pulmonary vein; internally with the ascending aorta; externally with the right phrenic nerve, and right lung. Immediately before entering the pericardium it receives the vena azygos major.
Fig. 135.*

**Iliac Veins.**

The *External iliac vein* lies to the inner side of the corresponding artery at the os pubis; but gradually gets behind it as it passes upwards along the brim of the pelvis, and terminates opposite the sacro-iliac symphysis by uniting with the internal iliac, to form the common iliac vein. Immediately above Poupart's ligament it receives the epigastric and circumflexa illi veins; it has no valves.

The *Internal iliac vein* is formed by vessels which correspond with the branches of the internal iliac artery; it receives the returning blood from the gluteal, ischiatic, internal pudic, and obturator veins, externally to the pelvis; and from the vesical and uterine plexuses within the pelvis. The vein lies to the inner side of the internal iliac artery, and terminates by uniting with the external iliac vein, to form the common iliac.

The *Vesical and prostatic plexus* is an important plexus of veins which surrounds the neck and base of the bladder and prostate gland, and receives its blood from the great dorsal vein of the penis, and from the veins of the external organs of generation. It is retained in connection with the sides of the bladder by a reflexion of the pelvic fascia.

The *Uterine plexus* is situated around the vagina, and upon the sides of the uterus, between the two layers of the broad ligaments. The veins forming the vesical and uterine plexus are very subject to the production of phlebolites.

The *Common iliac veins* are formed by the union of the external and internal iliac vein on each side of the pelvis. The *right* common iliac, shorter than the left, ascends obliquely behind the corresponding artery; and upon the intervertebral substance between the fourth and fifth lumbar vertebrae, unites with the vein of the opposite side, to form the inferior cava. The left common iliac, longer and more oblique than the right, ascends behind, and a little internally to the corresponding artery, and passes beneath the right common iliac artery, near its origin, to unite with the right vein in the formation of the inferior vena cava. The right common iliac vein has no branch opening into it; the left receives the vena sacra media. These veins have no valves.

**INFERIOR VENA CAVA.**

The *inferior vena cava* is formed by the union of the two common iliac veins, upon the intervertebral substance between the fourth and fifth lumbar vertebra. It ascends along the front of the vertebral column, on the right side of the abdominal aorta, and passing through the fissure in the posterior border of the liver and the quadrilateral opening in the tendinous centre of the diaphragm, terminates in the inferior and posterior part of the right auricle. There are no valves in this vein.

It is in relation from below upwards, *in front* with the mesentery transverse duodenum, portal vein, pancreas, and liver, which latter nearly and sometimes completely surrounds it; *behind* it rests upon the vertebral column and right crus of the diaphragm, from which it is separated by the right renal and lumbar arteries; to the *right* it has the peritoneum and sympathetic nerve; and to the *left* the aorta.

The *Branches* which the inferior cava receives in its course, are the—

- Lumbar,
- Right spermatic,
- Renal,
- Supra-renal,
- Phrenic,
- Hepatic.

ternal iliac vein. 11. The common iliac veins; the small vein between these is the vena sacra media. 12, 12. Lumbar veins. 13. The right spermatic vein. 14. The left spermatic, opening into the left renal vein. 15. The right renal vein. 16. The trunk of the hepatic veins. 17. The greater vena azygos, commencing inferiorly in the lumbar veins. 18. The lesser vena azygos, also commencing in the lumbar veins. 19. A branch of communication with the left renal vein. 20. The termination of the lesser in the greater vena azygos. 21. The superior intercostal vein; communicating inferiorly with the lesser vena azygos, and terminating superiorly in the left vena innominata.
The Lumbar veins, three or four in number on each side, collect the venous blood from the muscles and integument of the loins, and from the spinal veins: the left are longer than the right from the position of the vena cava.

The Right spermatic vein is formed by the two veins which return the blood from the venous plexus, situated in the spermatic cord. These veins follow the course of the spermatic artery, and unite to form the single trunk which opens into the inferior vena cava. The left spermatic vein terminates in the left renal vein.

The Ovarian veins represent the spermatic veins of the male, and collect the venous blood from the ovaries, round ligaments, and Fallopian tubes, and communicate with the uterine sinuses. They terminate as in the male.

The Renal or emulgent veins return the blood from the kidneys; their branches are situated in front of the divisions of the renal arteries, and the left opens into the vena cava somewhat higher than the right. The left is longer than the right in consequence of the position of the vena cava, and crosses the aorta immediately below the origin of the superior mesenteric artery. It receives the left spermatic vein, which terminates in it at right angles: hence the more frequent occurrence of varicocele on the left than on the right side.

The Supra-renal veins terminate partly in the renal veins, and partly in the inferior vena cava.

The Phrenic veins return the blood from the ramifications of the phrenic arteries; they open into the inferior cava.

The Hepatic veins form two principal trunks and numerous smaller veins which open into the inferior cava, while that vessel is situated in the posterior border of the liver. The hepatic veins commence in the liver by minute venules, the intralobular veins, in the centre of each lobule; these pour their blood into larger vessels, the sublobular veins; and the sublobular veins constitute by their convergence and union, the hepatic trunks, which terminate in the inferior vena cava.

azygos veins.

The azygos veins form a system of communication between the superior and inferior vena cava, and serve to return the blood from that part of the trunk of the body in which those vessels are deficient, on account of their connection with the heart. This system consists of three vessels, the

Vena azygos major,
Vena azygos minor,
Superior intercostal vein.

The Vena azygos major commences in the lumbar region by a communication with the lumbar veins; sometimes it is joined by a branch directly from the inferior vena cava, or by one from the renal vein.
VERTEBRAL AND SPINAL VEINS.

It passes through the aortic opening in the diaphragm, and ascends upon the right side of the vertebral column to the third dorsal vertebra, where it arches forwards over the right bronchus, and terminates in the superior cava. It receives all the intercostal veins of the right side, the vena azygos minor, and the bronchial veins.

The \textit{Vena azygos minor} commences in the lumbar region, on the left side, by a communication with the lumbar or renal veins. It passes beneath the border of the diaphragm, and ascending upon the left side of the vertebral column crosses the fifth or sixth dorsal vertebra to open into the vena azygos major. It receives the six or seven lower intercostal veins of the left side. The azygos veins have no valves.

The \textit{Superior intercostal vein} is the trunk formed by the union of the five or six upper intercostal veins of the left side. It communicates below with the vena azygos minor, and ascends to terminate in the left vena innominata.

VERTEBRAL AND SPINAL VEINS.

The numerous venous plexuses of the vertebral column and spinal cord may be arranged into three groups:—

Dorsi-spinal,
Meningo-rachidian,
Medulli-spinal.

The \textit{Dorsi-spinal veins} form a plexus around the spinous, transverse and articular processes, and arches of the vertebrae. They receive the returning blood from the dorsal muscles and surrounding structures, and transmit it, in part to the meningo-rachidian, and in part to the vertebral, intercostal, lumbar, and sacral veins.

The \textit{Meningo-rachidian veins} are situated between the theca vertebralis and the vertebrae. They communicate freely with each other by means of a complicated plexus. In front they form two longitudinal trunks, (\textit{longitudinal spinal sinuses}), which extend the whole length of the column on each side of the posterior common ligament, and are joined on the body of each vertebra by transverse trunks, which pass beneath the ligament, and receive the large basi-vertebral veins from the interior of each vertebra. The meningo-rachidian veins communicate superiorly through the anterior condyloid foramina with the internal jugulars; in the neck they pour their blood into the vertebral veins; in the thorax, into the intercostals; and in the loins and pelvis into the lumbar and sacral veins, the communications being established through the intervertebral foramina.

The \textit{Medulli-spinal veins} are situated between the pia mater and arachnoid; they communicate freely with each other to form plexuses, and send branches through the intervertebral foramina with each of the spinal nerves, to join the veins of the trunk.
CARDIAC VEINS.

The veins returning the blood from the substance of the heart, are the—

Great cardiac vein,
Posterior cardiac veins,
Anterior cardiac veins,
Venæ Thebesii.

The Great cardiac vein (coronary) commences at the apex of the heart, and ascends along the anterior ventricular groove to the base of the ventricles; it then curves around the left auriculo-ventricular groove to the posterior part of the heart, where it terminates in the right auricle. It receives in its course the left cardiac veins from the left auricle and ventricle, and the posterior cardiac veins from the posterior ventricular groove.

The Posterior cardiac vein, frequently two in number, commences also at the apex of the heart, and ascends along the posterior ventricular groove, to terminate in the great cardiac vein. It receives the veins from the posterior aspect of the two ventricles.

The Anterior cardiac veins collect the blood from the anterior surface of the right ventricle; one larger than the rest runs along the right border of the heart and joins the trunk formed by these veins, which curves around the right auriculo-ventricular groove, to terminate in the great cardiac vein near its entrance into the right auricle.

The Venæ Thebesii are numerous minute venules which convey the venous blood directly from the substance of the heart into its four cavities. Their existence is denied by some anatomists.

PORTAL SYSTEM.

The portal system is composed of four large veins which return the blood from the chylopoietic viscera; they are the—

Inferior mesenteric vein,
Superior mesenteric vein,
Splenic vein,
Gastric veins.

The Inferior mesenteric vein receives its blood from the rectum by means of the haemorrhoidal veins, and from the sigmoid flexure and descending colon, and ascends behind the transverse duodenum and pancreas, to terminate in the splenic vein. Its haemorrhoidal branches inosculate with the branches of the internal iliac vein, and thus establish a communication between the portal and general venous system.

The Superior mesenteric vein is formed by branches which collect
the venous blood from the capillaries of the superior mesenteric artery; they constitute by their junction a large trunk, which ascends by the side of the corresponding artery, crosses the transverse duodenum, and unites behind the pancreas with the splenic in the formation of the portal vein.

The Splenic vein commences in the structure of the spleen, and quits

*Fig. 136.*

* The portal vein. 1. The inferior mesenteric vein; it is traced by means of dotted lines behind the pancreas (2) to terminate in the splenic vein (3). 4. The spleen. 5. Gastric veins, opening into the splenic vein. 6. The superior mesenteric vein. 7. The descending portion of the duodenum. 8. Its transverse portion, which is crossed by the superior mesenteric vein and by a part of the trunk of the superior mesenteric artery. 9. The portal vein. 10. The hepatic artery. 11 The ductus communis choledochus. 12. The division of the duct and vessels at the transverse fissure of the liver. 13. The cystic duct leading to the gall bladder.
that organ by several large veins; it is larger than the splenic artery, and perfectly straight in its course. It passes horizontally inwards behind the pancreas, and terminates near its greater end by uniting with the superior mesenteric and forming the portal vein. It receives in its course the gastric and pancreatic veins, and near its termination the inferior mesenteric vein.

The *Gastric veins* correspond with the gastric, gastro-epiploic, and vasa brevia arteries, and terminate in the splenic vein.

The *Vena portae*, formed by the union of the splenic and superior mesenteric vein behind the pancreas, ascends through the right border of the lesser omentum to the transverse fissure of the liver, where it divides into two branches, one for each lateral lobe. In the right border of the lesser omentum it is situated behind and between the hepatic artery and ductus communis choledochus, and is surrounded by the hepatic plexus of nerves and lymphatics. At the transverse fissure each primary branch divides into numerous secondary branches which ramify through the portal canals, and give off vaginal and interlobular veins, and the latter terminate in the lobular venous plexus of the lobules of the liver. The portal vein within the liver receives the venous blood from the capillaries of the hepatic artery.

**PULMONARY VEINS.**

The pulmonary veins, four in number, return the arterial blood from the lungs to the left auricle of the heart; they differ from the veins in general, in the area of their cylinders being very little larger than the corresponding arteries, and in accompanying singly each branch of the pulmonary artery. They commence in the capillaries upon the parietes of the bronchial cells, and unite to form a single trunk for each lobe. The vein of the middle lobe of the right lung unites with the superior vein so as to form the two trunks which open into the left auricle. Sometimes they remain separate, and then there are three pulmonary veins on the right side. The right pulmonary veins pass behind the superior vena cava to the left auricle, and the left behind the pulmonary artery; they both pierce the pericardium. Within the lung the branches of the pulmonary veins are behind the bronchial tubes, and those of the pulmonary artery in front; but at the root of the lungs the veins are in front, next the arteries, and then the bronchi. There are no valves in the pulmonary veins.
CHAPTER VII.

ON THE LYMPHATICS.

The lymphatic vessels, or absorbents, have received their double appellation from certain phenomena which they present; the former name being derivable from the appearance of the limpid fluid (lympha, water) which they convey; and the latter, from their supposed property of absorbing foreign substances into the system. They are minute, delicate, and transparent vessels, remarkable for their general uniformity of size, for a knotted appearance which is due to the presence of numerous valves, for the frequent dichotomous divisions which occur in their course, and for their division into several branches immediately before entering a gland. Their office is to collect the products of digestion and the detrita of nutrition, and convey them into the venous circulation near to the heart.

Lymphatic vessels commence in a delicate network which is distributed upon the cutaneous surface of the body, upon the various surfaces of organs and throughout their internal structure; and from this network the lymphatic vessels proceed, nearly in straight lines, in a direction towards the root of the neck. In their course they are intercepted by numerous small spheroid or oblong bodies, more or less flattened on their surface, lymphatic glands. The lymphatic vessels entering these glands are termed vasa inferentia or afferentia, and those which quit them vasa efferentia. The vasa inferentia vary in number from two to six, they divide at the distance of a few lines from the gland into several smaller vessels and enter it by one of the flattened surfaces.* The vasa efferentia escape from the gland on the opposite, but not unfrequently on the same surface; they consist like the vasa inferentia at their junction with the gland of several small vessels which unite after a course of a few lines to form from one to three trunks, often twice as large as the vasa inferentia.

Lymphatic vessels admit of a threefold division into superficial, deep, and lacteals. The superficial lymphatic vessels, upon the surface of the body, follow the course of the veins, and pierce the deep fascia in convenient situations, to join the deep lymphatics. Upon the surface of organs they converge to the nearest lymphatic trunks. The superficial lymphatic glands are placed in the most protected situations.

* See Mr. Lane's article on the "Lymphatic System," in the Cyclopaedia of Anatomy and Physiology.
of the superficial fascia, as in the hollow of the ham and groin in the lower extremity, and upon the inner side of the arm in the upper extremity.

The deep lymphatics, fewer in number and somewhat larger than the superficial vessels, accompany the deeper veins; those from the lower parts of the body converging to the numerous glands seated around the iliac veins and inferior vena cava, and terminating in a large trunk situated upon the vertebral column, the thoracic duct. From the upper part of the trunk of the body on the left side, and from the left side of the head and neck, they also proceed to the thoracic duct. Those on the right side of the head and neck, right upper extremity, and right side of the thorax, form a distinct duct which terminates at the point of junction of the subclavian with the internal jugular vein on the right side of the root of the neck.

The lacteals are the lymphatic vessels of the small intestines; they have received their distinctive appellation from conveying the milk-like product of digestion, the chyle, to the great centre of the lymphatic system, the thoracic duct. They are situated in the mesentery, and pass through the numerous mesenteric glands in their course.

Lymphatic vessels are very generally distributed through the animal tissues; there are, nevertheless, certain structures in which they have never been detected, for example, the brain and spinal cord, the eye, bones, cartilages, tendons, the membranes of the ovum, the umbilical cord, and the placenta. The anastomoses between these vessels are less frequent than between arteries and veins; they are effected by means of vessels of equal size with the vessels which they connect, and no increase of calibre results from their junction. The lymphatic vessels are smallest in the neck, larger in the upper extremities, and larger still in the lower limbs.

For the purpose of effecting the movement of their fluids in a proper direction, lymphatic vessels are furnished with valves, and it is to these that the appearance of constrictions around the cylinders of the vessels at short distances is due. Like the valves of veins, the valves of lymphatic vessels are each composed of two semilunar flaps attached by their convex border to the sides of the vessel and free by their concave border. This is the general character of the valves, but, as in veins, there are exceptions in their form and disposition; sometimes one flap is so small as to be merely rudimentary, while the other is large in proportion; sometimes the flap runs all the way round the tube, leaving a central aperture which can only be closed by a contractile power in the valve itself; and sometimes instead of being circular the aperture is elliptical, and the arrangement of the flaps like that of the ileo-cæcal valve.* These peculiarities are most frequently met with at and near the anastomoses of the lymphatic vessels. The valves are most numerously met with near the lymphatic glands; next in frequency they are found in the neck and upper extremities where

* Mr. Lane, loc. cit.
the vessels are small, and least numerously in the lower limbs where the lymphatics are larger. In the thoracic duct an interspace of two or three inches frequently occurs between the valves. Connected with the presence of valves in the lymphatic vessels, are two lateral dilatations or pouches, analogous to the valvular sinuses of veins. These sinuses are situated on the cardiac side of the valves; they receive the valves when the latter are thrown back by the current of the blood; and when reflux occurs, they become distended with a body of fluid which makes pressure on the flaps. These pouch-like dilatations and the constrictions corresponding with the line of attachment of the convex borders of the flaps are the cause of the knotted appearance of distended lymphatic vessels.

Like arteries and veins, lymphatic vessels are composed of three coats, external, middle and internal. The external coat is cellulos-fibrous, like that of blood-vessels; it is thin, but very strong, and serves to connect the vessel to surrounding tissues, at the same time that it forms a protective covering. The middle coat is thin and elastic, and consists of a layer of longitudinal fibres analogous to those of the innermost layer of the middle coat of arteries and veins. Some few circular fibres may be seen externally to these in the larger lymphatic vessels. The internal coat is inelastic and more liable to rupture than the other coats. It is a serous layer continuous with the lining membrane of the veins, and invested by an epithelium. The valves are composed of a very thin layer of fibrous tissue coated on its two surfaces by epithelium.

The lymphatic glands (conglobate, absorbent) are small oval and somewhat flattened or rounded bodies, composed of a plexus of minute lymphatic vessels, associated with a plexus of blood-vessels, and enclosed in a thin cellular capsule. When examined on the surface they are seen to have a lobulated appearance, while the face of a section is cellular from the division of the numberless convolutions which are formed by the lymphatic vessels within its substance. The colour of the glands is a pale pink, excepting those of the lungs, the bronchial glands, which in the adult are more or less mottled with black, and are sometimes filled with a black pigment. Lymphatic glands are larger in the young subject than in the adult, and are smallest in old age; they as well as their vessels are supplied with arteries, veins and nerves, like other structures.

I shall describe the lymphatic vessels and glands according to the arrangement adopted for the veins, commencing with those of the head and neck, and proceeding next to those of the upper extremity, lower extremity, and trunk.

LYMPHATICS OF THE HEAD AND NECK.

The Superficial lymphatic glands of the head and face are small, few in number, and isolated; they are the occipital, which are situated
LYMPHATICS OF THE UPPER EXTREMITY.

near the origin of the occipito-frontalis muscle; posterior auricular, behind the ear; parotid, in the parotid gland; zygomatic, in the zygomatic fossa; buccal, upon the buccinator muscle; and submaxillary, beneath the margin of the lower jaw. There are no deep lymphatic glands within the cranium.

The Superficial cervical lymphatic glands are few in number and small; they are situated in the course of the external jugular vein, between the sterno-mastoid and trapezius muscles, at the root of the neck, and about the larynx.

The Deep cervical glands (glandulae concatenatae) are numerous and of large size; they are situated around the internal jugular vein and sheath of the carotid arteries, by the side of the pharynx, oesophagus, and trachea, and extend from the base of the skull to the root of the neck, where they are in communication with the lymphatic vessels and glands of the thorax.

The Superficial lymphatic vessels of the head and face are disposed in three groups; occipital, which take the course of the occipital vein to the occipital and deep cervical glands; temporal, which follow the branches of the temporal vein to the parotid and deep cervical glands; and facial, which accompany the facial vein to the submaxillary lymphatic glands.

The Deep lymphatic vessels of the head are the meningeal and cerebral; the former are situated in connection with the meningeal veins, and escape through foramina at the base of the skull, to join the deep cervical glands. The cerebral lymphatics, according to Fohmann, are situated upon the surface of the pia mater, none having yet been discovered in the substance of the brain. They pass most probably through the foramina at the base of the skull, to terminate in the deep cervical glands.

The Deep lymphatic vessels of the face proceed from the nasal fossae, mouth, and pharynx, and terminate in the submaxillary and deep cervical glands.

The Superficial and deep cervical lymphatic vessels accompany the jugular veins, passing from gland to gland, and at the root of the neck communicate with the thoracic lymphatic vessels, and terminate, on the right side, in the ductus lymphaticus dexter, and, on the left, in the thoracic duct, near its termination.

LYMPHATICS OF THE UPPER EXTREMITY.

The Superficial lymphatic glands of the arm are not more than four or five in number, and of very small size. One or two are situated near the median basilic and cephalic veins, at the bend of the elbow; and one or two near the basilic vein, on the inner side of the upper arm, immediately above the elbow.

The Deep glands in the fore-arm are excessively small and infrequent; two or three may generally be found in the course of the
radial and ulnar vessels. In the upper arm there is a chain of small glands, accompanying the brachial artery.

The *Axillary glands* are numerous and of large size. Some are closely adherent to the vessels, others are dispersed in the loose areolar tissue of the axilla, and a small chain may be observed extending along the lower border of the pectoralis major to the mammary gland. Two or three subclavian glands are situated beneath the clavicle, and serve as the medium of communication between the axillary and deep cervical lymphatic glands.

The *Superficial lymphatic vessels* of the upper extremity commence upon the fingers and take their course along the fore-arm to the bend of the elbow. The greater part reach their destination by passing along the dorsal surface of the fingers, wrist, and fore-arm, and then curving around the borders of the latter; but some few are met with in the palm of the hand, which take the direction of the median vein. At the bend of the elbow the lymphatics arrange themselves into two groups; an internal and larger group, which communicates with a gland situated just above the inner condyle, and then accompanies the basilic vein upwards to the axilla to enter the axillary glands; and a small group which follows the course of the cephalic vein. Several of the vessels of this group cross the biceps muscle at its upper part to enter the axillary glands, while the remainder, two or three in number, ascend with the cephalic vein in the interspace of the deltoïd and pectoralis major; they usually join a small gland in this space, and then cross the pectoralis minor muscle to become continuous with the subclavian lymphatics.

Besides the lymphatic vessels of the arm, the axillary glands receive those from the integument of the chest, its anterior, posterior, and lateral aspect, and the lymphatics of the mammary gland.

The *Deep lymphatics* accompany the vessels of the upper extremity, and communicate occasionally with the superficial lymphatics. They enter the axillary and subclavian glands, and at the root of the neck terminate on the left side in the thoracic duct, and on the right side in the ductus lymphaticus dexter.

**LYMPHATICS OF THE LOWER EXTREMITY.**

The *Superficial lymphatic glands* of the lower extremity are those of the groin, the *inguinal*; and one or two situated in the superficial fascia of the posterior aspect of the thigh, just above the popliteal region.

The *Inguinal glands* are divisible into two groups; a superior group of small size, situated along the course of Poupart's ligament, and receiving the lymphatic vessels from the parietes of the abdomen, gluteal region, perineum, and genital organs; and an inferior group of larger glands clustered around the internal saphenous vein near its
termination, and receiving the superficial lymphatic vessels from the lower extremity.

The Deep lymphatic glands are the anterior tibial, popliteal, deep inguinal, gluteal, and ischiatic.

The Anterior tibial is generally a single gland, placed on the interosseous membrane, by the side of the anterior tibial artery in the upper part of its course.

The Popliteal glands, four or five in number and small, are embedded in the loose areolar tissue and fat of the popliteal space.

The Deep inguinal glands, less numerous and smaller than the superficial, are situated near the femoral vessels in the groin, beneath the fascia lata.

The Gluteal and ischiatic glands are placed near the vessels of that name, above and below the pyriformis muscle at the great ischiatic foramen.

The Superficial lymphatic vessels are divisible into two groups, internal and external; the internal and principal group commencing on the dorsum and inner side of the foot, ascend the leg by the side of the internal saphenous vein, and passing behind the inner condyle of the femur, follow the direction of that vein to the groin, where they join the saphenous group of superficial inguinal glands. The greater part of the efferent vessels from these glands pierce the cribiform fascia of the saphenous opening and the sheath of the femoral vessels, to join the lymphatic gland situated in the femoral ring, which serves to establish a communication between the lymphatics of the lower extremity and those of the trunk. The other efferent vessels pierce the fascia lata to join the deep glands. The vessels which pass upwards from the outer side of the dorsum of the foot, ascend upon the outer side of the leg, and curve inwards just below the knee, to unite with the lymphatics of the inner side of the thigh. The external group consists of a few lymphatic vessels which commence upon the outer side of the foot and posterior part of the ankle, and accompany the external saphenous vein to the popliteal region, where they enter the popliteal glands.

The Deep lymphatic vessels accompany the deep veins, and communicate with the various glands in their course. After joining the deep inguinal glands they pass beneath Poupart's ligament, to communicate with the numerous glands situated around the iliac vessels. The deep lymphatics of the gluteal region follow the course of the branches of the gluteal and ischiatic arteries. The former join the glands situated upon the upper border of the pyriformis muscle, and the latter, after communicating with the lymphatics of the thigh, enter the ischiatic glands.

LYMPHATICS OF THE TRUNK.

The lymphatics of the trunk may be arranged under three heads, superficial, deep, and visceral.
The **Superficial lymphatic vessels** of the upper half of the trunk pass upwards and outwards on each side, and converge, some to the axillary glands, and others to the glands at the root of the neck. The lymphatics from the mammary glands follow the lower border of the pectoralis major, communicating, by means of a chain of lymphatic glands, with the axillary glands. The superficial lymphatic vessels of the lower half of the trunk, of the gluteal region, perineum, and external organs of generation, converge to the superior group of superficial inguinal glands. Some small glands are situated on each side of the dorsal vein of the penis, near the suspensory ligament; from these, as from the superficial lymphatics, the efferent vessels pass into the superior group of superficial inguinal glands.

The **Deep lymphatic glands of the thorax** are the intercostal, internal mammary, anterior mediastinal, and posterior mediastinal.

The **Intercostal glands** are of small size, and are situated on each side of the vertebral column, near the articulations of the heads of the ribs, and in the course of the intercostal arteries.

The **Internal mammary glands** also very small, are placed in the intercostal spaces, by the side of the internal mammary arteries.

The **Anterior mediastinal glands** occupy the loose areolar tissue of the anterior mediastinum, resting some on the diaphragm, but the greater number upon the large vessels at the root of the heart.

The **Posterior mediastinal glands** are situated along the course of the aorta and oesophagus in the posterior mediastinum, and communicate above with the deep cervical glands, on each side with the intercostal and below with the abdominal glands.

The **Deep lymphatic vessels of the thorax** are the intercostal, internal mammary, and diaphragmatic.

The **Intercostal** lymphatic vessels follow the course of the arteries of the same name; and reaching the vertebral column curve downwards, to terminate in the thoracic duct.

The **Internal mammary** lymphatics commence in the paries of the abdomen, communicating with the epigastric lymphatics. They ascend by the side of the internal mammary vessels, being joined in their course by the anterior intercostals, and terminate at the root of the neck, on the right side in the tributaries of the ductus lymphaticus dexter, and on the left in the thoracic duct. The **diaphragmatic** lymphatics pursue the direction of their corresponding veins, and terminate some in front in the internal mammary vessels, and some behind, in the posterior mediastinal lymphatics.

The **Deep lymphatic glands of the abdomen** are the lumbar glands; they are very numerous, and are seated around the common iliac vessels, the aorta and vena cava.

The deep lymphatic glands of the pelvis are the external iliac, internal iliac and sacral.

The **External iliac** are placed around the external iliac vessels, being in continuation by one extremity with the femoral lymphatics, and by the other with the lumbar glands.
LYMPHATICS OF THE VISCERA.

The Internal iliac glands are situated in the course of the internal iliac vessels, and the sacral glands are supported by the concave surface of the sacrum.

The Deep lymphatic vessels are continued upwards from the thigh, beneath Poupart's ligament, and along the external iliac vessels to the lumbar glands, receiving in their course the epigastric, circumflexa ili, and ilio-lumbar lymphatic vessels. Those from the parietes of the pelvis, and from the gluteal, ischiatic, and obturator vessels, follow the course of the internal iliac arteries, and unite with the lumbar lymphatics. And the lumbar lymphatic vessels, after receiving all the lymphatics from the lower extremities, pelvis, and loins, terminate by several large trunks in the receptaculum chyli.

LYMPHATICS OF THE VISCERA.

The Lymphatic vessels of the lungs are of large size, and are distributed over every part of the surface, and through the texture of these organs; they converge to the numerous glands situated around the bifurcation of the trachea and roots of the lungs, the bronchial glands. Some of these glands of small size, may be traced in connection with the bronchial tubes for some distance into the lungs. The efferent vessels from the bronchial glands unite with the tracheal and esophageal glands, and terminate principally in the thoracic duct at the root of the neck, and partly in the ductus lymphaticus dexter. The bronchial glands, in the adult, present a variable tint of brown, and in old age a deep black colour. In infancy they have none of this pigment, and are not to be distinguished from lymphatic glands in other situations.

The Lymphatic vessels of the heart originate in the subserous areolar tissue of the surface, and in the deeper tissues of the organ, and follow the course of the vessels, principally, along the right border of the heart to the glands situated around the arch of the aorta and the bronchial glands, whence they proceed to the root of the neck, and terminate in the thoracic duct.

The Pericardiac and thymic lymphatic vessels proceed to join the anterior mediastinal and bronchial glands.

The Lymphatic vessels of the liver are divisible into the deep and superficial. The former take their course through the portal canals, and through the right border of the lesser omentum, to the lymphatic glands situated in the course of the hepatic artery and along the lesser curve of the stomach. The superficial lymphatics are situated in the areolar structure of the proper capsule, over the whole surface of the liver. Those of the convex surface are divided into two sets;—1. Those which pass from before backwards; 2. Those which advance from behind forwards. The former unite to form trunks, which enter between the folds of the lateral ligaments at the right
and left extremities of the organ, and of the coronary ligament in the middle. Some of these pierce the diaphragm and join the posterior mediastinal glands; others converge to the lymphatic glands situated around the inferior cava. Those which pass from behind forwards consist of two groups: one ascends between the folds of the broad ligament, and perforates the diaphragm, to terminate in the anterior mediastinal glands; the other curves around the anterior margin of the liver to its concave surface, and from thence to the glands in the right border of the lesser omentum. The lymphatic vessels of the concave surface are variously distributed, according to their position; those from the right lobe terminate in the lumbar glands; those from the gall-bladder which are large and form a remarkable plexus, enter the glands in the right border of the lesser omentum; and those from the left lobe converge to the lymphatic glands, situated along the lesser curve of the stomach.

The Lymphatic glands of the spleen are situated around its hilus, and those of the pancreas in the course of the splenic vein. The lymphatic vessels of these organs pass through their respective glands, and join the aortic glands, previously to terminating in the thoracic duct.

The Lymphatic glands of the stomach are of small size, and are situated along the lesser and greater curves of that organ. The lymphatic vessels, as in other viscera, are superficial and deep, the former originating in the subserous and the latter in the submucous tissue; they pass from the stomach in four different directions: some ascend to the glands, situated along the lesser curve, others descend to those occupying the greater curve, a third set passes outwards to the splenic glands, and a fourth to the glands situated near the pylorus and to the aortic glands.

The Lymphatic glands of the small intestine are situated between the layers of the mesentery, in the meshes formed by the superior mesenteric artery, and are thence named mesenteric glands. These glands are most numerous and largest, superiorly, near the duodenum; and, inferiorly, near the termination of the ileum.

The Lymphatic vessels of the small intestines are of two kinds: those of the structure of the intestines, which run upon its surface previously to entering the mesenteric glands; and those which commence in the villi, upon the surface of the mucous membrane, and are named lacteals.

The Lacteals, according to Henle, commence in the centre of each villus as a coecal tubulus, which opens into a fine network, situated in the sub-mucous tissue. From this areolar network the lacteal vessels proceed to the mesenteric glands, and from thence to the thoracic duct, in which they terminate.

The Lymphatic glands of the large intestines are situated along the attached margin of the intestine, in the meshes formed by the arteries previously to their distribution. The lymphatic vessels take their course in two different directions; those of the cecum, ascending and transverse colon, after traversing their proper glands, proceed to the
mesenteric, and those of the descending colon and rectum to the lumbar glands.

The Lymphatic vessels of the kidney follow the direction of the blood-vessels to the lumbar glands situated around the aorta and inferior vena cava; those of the supra-renal capsules, which are very large and numerous, terminate in the renal lymphatics.

The Lymphatic vessels of the viscera of the pelvis terminate in the sacral and lumbar glands.

The Lymphatic vessels of the testicle take the course of the spermatic cord in which they are of large size; they terminate in the lumbar glands.

THORACIC DUCT.

The thoracic duct* commences in the abdomen, by a considerable and somewhat triangular dilatation, the receptaculum chyli, which is situated upon the front of the body of the second lumbar vertebra, behind and between the aorta and inferior vena cava, and close to the tendon of the right crus of the diaphragm. From the upper part of the receptaculum chyli the thoracic duct ascends through the aortic opening of the diaphragm, and along the front of the vertebral column, lying between the thoracic aorta and vena azygos, to the fourth dorsal vertebra. It then inclines to the left side, passes behind the arch of the aorta, and ascends by the side of the oesophagus and behind the perpendicular portion of the left subclavian artery to the root of the neck opposite the seventh cervical vertebra, where it makes a sudden curve forwards and downwards, and terminates at the point of junction of the left subclavian with the left internal jugular vein.

The thoracic duct is equal in size to the diameter of a goose-quill at its commencement from the receptaculum chyli, diminishes considerably in diameter towards the middle of the posterior mediastinum, and again becomes dilated near its termination. At about the middle of its course it frequently divides into two branches of equal size, which reunite after a short course; and sometimes it gives off several branches, which assume a plexiform arrangement in this situation. Occasionally the thoracic duct bifurcates at the upper part of the thorax into two branches, one of which opens into the point of junction between the right subclavian and jugular veins, while the other proceeds to the normal termination of the duct on the left side. In rare instances the duct has been found to terminate in the vena azygos, which is its normal destination in some Mammalia.

The thoracic duct presents fewer valves in its course than lym-

* The thoracic duct was discovered by Eustachius, in 1563, in the horse; he regarded it as a vein, and called it the vena alba thoracis. The lacteals were first seen by Asellius in 1622, in the dog; and within the next ten years by Veslingius in man.
phatic vessels generally; at its termination it is provided with a pair of semilunar valves, which prevent the admission of venous blood into its cylinder.

Branches.—The thoracic duct receives at its commencement four or five large lymphatic trunks, which unite to form the receptaculum chyli; it next receives the trunks of the lacteal vessels. Within the thorax it is joined by a large lymphatic trunk from the liver, and in its course through the posterior mediastinum, receives the lymphatic vessels both from the viscerae and from the parietes of the thorax. At its curve forwards in the neck it is joined by the lymphatic trunks from the left side of the head and neck, left upper extremity, and from the upper part of the thorax, and thoracic viscerae.

The Ductus lymphaticus dexter is a short trunk which receives the lymphatic vessels from the right side of the head and neck, right upper extremity, right side of the thorax, right lung, and one or two branches from the liver, and terminates at the junction of the

In the spinal cord
If the fetus one find a
longitudinal canal up to
the 4th month, subsequently
this is filled up by the
deposition of gray nervous
matter: it is a curious
coincidence that the
annouement of the fetus
begin to be appreciated by
the mother about this
time.
CHAPTER VIII.

ON THE NERVOUS SYSTEM.

The nervous system consists of a central organ, the cerebro-spinal centre or axis, and of numerous rounded and flattened white cords, the nerves, which are connected by one extremity with the cerebro-spinal centre, and by the other are distributed to all the textures of the body. The sympathetic system is an exception to this description; for in place of one it has many small centres which are called ganglia, and which communicate very freely with the cerebro-spinal axis and with its nerves.

The cerebro-spinal axis consists of two portions, the brain, an organ of large size, situated within the skull, and the spinal cord, a lengthened portion of the nervous centre continuous with the brain, and occupying the canal of the vertebral column.

The most superficial examination of the brain and spinal cord shews them to be composed of fibres, which in some situations are ranged side by side or collected into bundles or fasciculi, and in other situations are interlaced at various angles by cross fibres. The fibres are connected and held together by a delicate areolar web, which forms the bond of support to the entire organ. It is also observed that the cerebro-spinal axis presents two substances differing from each other in density and colour; a grey or cineritious or cortical substance, and a white or medullary substance. The grey substance forms a thin lamella over the entire surface of the convolutions of the cerebrum, and the laminae of the cerebellum: hence it has been named cortical; but the grey substance is not confined to the surface of the brain, as this term would imply; it is likewise situated in the centre of the spinal cord its entire length, and may be thence traced through the medulla oblongata, crura cerebri, thalami optici, and corpora striata; it enters also into the composition of the locus perforatus, tuber cinereum, commissura mollis, pineal gland, pituitary gland, and corpora rhomboidea.

The fibres of the cerebro-spinal axis are arranged into two classes, diverging and converging. The diverging fibres proceed from the medulla oblongata, and diverge to every part of the surface of the brain; while the converging commence upon the surface, and proceed inwards towards the centre so as to connect the diverging fibres of opposite sides. In certain parts of their course the diverging fibres are separated by the grey substance, and increase in number so as to form a body of considerable size, which is called a ganglion. The position
and mutual relations of these fibres and ganglia may be best explained by reference to the mode of development of the cerebro-spinal axis in animals and in man.

The centre of the nervous system in the lowest animals possessed of a lengthened axis, presents itself in the form of a double cord. A step higher in the animal scale, and knots or ganglia are developed upon one extremity of this cord; such is the most rudimentary condition of the brain in the lowest forms of vertebrata. In the lowest fishes the anterior extremity of the double cord displays a succession of five pairs of ganglia. The higher fishes and amphibia appear to have a different disposition of these primitive ganglia. The first two have become fused into a single ganglion, and then follow only three pairs of symmetrical ganglia. But if the larger pair be unfolded after being hardened in alcohol, it will then be seen that the whole number of ganglia exist, but that four have become concealed by a thin covering that has spread across them. This condition of the brain carries us upwards in the animal scale even to Mammalia; e.g., in the dog or cat we find, first a single ganglion, the cerebellum; then three pairs following each other in succession; and if we unfold the middle pair, we shall be at once convinced that it is composed of two pairs of primitive ganglia concealed by an additional development. Again it will be observed, that the primitive ganglia of opposite sides, at first separate and disjoined, become connected by means of transverse fibres of communication (commissures; commissura, a joining). The office of these commissures is the association in function of the two symmetrical portions. Hence we arrive at the general and important conclusion, that the brain among the lower animals consists of primitive cords, primitive ganglia upon those cords, and commissures which connect the substances of the adjoining ganglia, and associate their functions.

In the development of the cerebro-spinal axis in man, the earliest indication of the spinal cord is presented under the form of a pair of minute longitudinal filaments placed side by side. Upon these, towards the anterior extremity, five pairs of minute swellings are observed, not disposed in a straight line as in fishes, but curved upon each other so as to correspond with the direction of the future cranium. The posterior pair soon become cemented upon the middle line, forming a single ganglion; the second pair also unite with each other; the third and fourth pairs, at first distinct, are speedily veiled by a lateral development, which arches backwards and conceals them; the anterior pairs, at first very small, decrease in size and become almost lost in the increased development of the preceding pairs.

We see here a chain of resemblances corresponding with the progressive development observed in the lower animals; the human brain is passing through the phases of improving development, which distinguish the lowest from the lower creatures: and we are naturally led to the same conclusion with regard to the architecture of the human brain, that we were led to establish as the principle of development in
the inferior creatures, namely, that it is composed of primitive cords, primitive ganglia upon those cords, commissures to connect those ganglia, and developments from those ganglia.

In the adult, the primitive longitudinal cords have become cemented together, to form the spinal cord. But, at the upper extremity, they separate from each other under the name of crura cerebri. The first pair of ganglia developed from the primitive cords, have grown into the cerebellum; the second pair (the optic lobes of animals) have become the corpora quadrigemina of man. The third pair, the optic thalami, and the fourth, the corpora striata, are the basis of the hemispheres, which, the merest lamina in the fish, have become the largest portion of the brain in man. And the fifth pair (olfactory lobes), so large in the lowest forms, have dwindled into the olfactory bulbs of man.

The white substance of the brain and spinal cord when examined with the microscope, is found to consist of fibres embedded in granular matter. The fibres vary in diameter from $\frac{1}{3000}$ to $\frac{1}{4000}$ of an inch; the former is the measurement of the fibres where the white substance is accumulated in any quantity; the latter, where the fibres enter the grey substance, and between these admeasurements every intermediate size occurs. The fibres are composed of a thin, transparent, and structureless neurilemma, containing in the living body a pellucid, colourless, oil-like fluid (neurine). After death the nervous fluid coagulates, and then presents the appearance of a white, opake, curd-like matter, which aggregates in masses when the fibres are pressed or stretched, and gives to the nervous fibre a varicose form. The disposition of the nervous fibre to take on the varicose form bears a close relation to the thinness of the neurilemma; hence in the fibres of the brain and spinal cord, and also in those of the olfactory, optic, and auditory nerves, where the neurilemma is very thin, this character is most remarkable. The nervous fibres of the brain terminate in the grey substance by forming loops, as do the peripheral nerves in nearly all parts of the body.

The grey substance of the brain is composed of globular

* Minute structure of nerve. 1. The mode of termination of nerve-fibres in loops; three of these loops are simple, the fourth is convoluted. The latter is found in situations where an exalted degree of sensation exists. 2. A nerve-fibre from the brain, shewing the varicose appearance produced by traction or pressure. 3. A nerve-fibre enlarged to shew its structure,—namely, a tubular
cells embedded in a soft granular matter, which serves as a bond of connection between them. The cells vary in size from 1/1000 to 1/100 of an inch in diameter; they are of a reddish grey colour, and are composed of a moderately thick capsule, containing a soft granular pulp and a nucleolated nucleus adherent to the inner surface of the investing capsule. The contents of the nucleus are similar to those of the parent cell, and the nucleolus may be either single or granular. Besides the constituents of the nerve-cell, there are pigment granules in variable number, sometimes dispersed generally through the pulp, and sometimes collected into small clusters, and giving to the cell a various tint of grey. It is to these pigment-bearing cells, collected together in greater or smaller numbers, that different parts of the brain owe their relative degrees of intensity of grey. The general form of the nerve-cells is globular, but there are found mingled with the globular cells others of different shape. Some of these latter are oval, oblong, or flattened, but the most remarkable form is that which is termed caudate, from its sending off from its periphery one or more ceceal processes of variable length. From the capsules of the nerve-cells filaments are frequently given off, which serve to connect the cells together, and the number and arrangement of the cells offer many peculiarities in different parts of the cerebro-spinal mass.

Two kinds of grey substance are described by Rolando as existing in the spinal cord; the one (substantia cinerea spongiosa vasculosa) is the ordinary grey matter of the cord, and the other (substantia cinerea gelatinosa) forms part of the posterior cornua. The former resembles in structure the grey matter of the brain, while the latter is composed of small bodies resembling the blood corpuscles of the frog.

The nerves are divisible into two great classes; those which proceed directly from the cerebro-spinal axis, the cranial and spinal nerves, and constitute the system of animal life; and those which originate from a system of nervous centres, independent of the cerebro-spinal axis, but closely associated with that centre by numerous communications, the sympathetic system, or system of organic life.

The division of nerves into cranial and spinal is purely arbitrary, and depends upon the circumstance of the former passing through the foramina of the cranium, and the latter through those of the vertebral column. With respect to origin, all the cranial nerves, with the exception of the first, olfactory, proceed from the spinal cord, or from its immediate prolongation into the brain. The spinal nerves arise by two roots; anterior, which proceeds from the anterior segment envelope, and a contained substance, neurine. 4. A nerve-cell, shewing its composition of a granular-looking capsule and granular contents. 5. Its nucleus containing a nucleolus. 6. A nerve-cell from which several caudate processes are given off. It contains, like the preceding, a nucleolated nucleus. 7. The third constituent of the medullary masses, namely, granules, or rather minute cells. These are dispersed among the cerebral fibres in great numbers; they present every variety of size, and are many of them nucleated.
of the spinal cord, and possesses a motor function; and posterior, which is connected with the posterior segment, and bestows the faculty of sensation. The motor nerves of the cranium are shown by dissection to be continuous with the motor portion of the cord, and form one system with the motor roots of the spinal cord; while the nerves of sensation, always excepting the olfactory, are in like manner traced to the posterior segment of the cord, and form part of the system of sensation. To these two systems a third was added by Sir Charles Bell, the respiratory system, which consists of nerves associated in the function of respiration, and arising from the side of the upper part of the spinal cord in one continuous line, which he thence named the respiratory tract. The microscope has succeeded in making no structural distinction between the anterior and posterior roots of the spinal nerves; but the latter are remarkable from possessing a ganglion near their attachment with the cord. This ganglion is observed upon the posterior roots of all the spinal nerves, and also upon the corresponding root of the fifth cranial nerve, which is thence considered a spinal cranial nerve. Upon others of the cranial nerves a ganglion is found, which associates them in their function with the nerves of sensation, and establishes an analogy with the spinal nerves.

The researches of Mr. Grainger have made an important addition to our knowledge of the mode of connection of the nerves with the spinal cord; he has shown that both roots of the spinal nerves, as well as most of the cerebral, divide into two sets of filaments upon entering the cord, one set being connected to the grey substance, while the other is continuous with the white or fibrous part of the cord. The former he considers to be the agents of the excitomotory system of Dr. Marshall Hall; and the latter, the communication with the brain and the medium for the transmission of sensation and volition. He has not been able to trace the fibres which enter the grey substance to their termination; but he thinks it probable that the ultimate filaments of the posterior root join those of the anterior root; or in the words of Dr. Marshall Hall's system, that the incident fibres (sensitive) are continuous with the reflex (motor).

The connection of a nerve with the cerebro-spinal axis is called, for convenience of description, its origin: this term must not, however, be received literally, for each nerve is developed in the precise situation which it occupies in the body, and with the same relations that it possesses in after life. Indeed, we not unfrequently meet with instances in anencephalous fetuses where the nerves are beautifully and completely formed, while the brain and spinal cord are wanting. The word "origin" must therefore be considered as a relict of the darkness of preceding ages, when the cerebro-spinal axis was looked upon as the tree from which the nerves pushed forth as branches. In their distribution the spinal nerves for the most part follow the course of the arteries, particularly in the limbs, where they lie almost constantly to the outer side and superficially to the vessels, as if for the purpose of receiving the first intimation of danger and of
communicating it to the muscles, that the latter may instantly remove the arteries from impending injury.

The microscopic examination of a cerebro-spinal nerve shows it to be composed of minute fibres, resembling those of the brain, and consisting of a neurilemma enclosing a pellucid fluid during life, and an opaque, white, curd-like substance after death. The chief difference between the fibres of the nerves and the cerebral fibres is the larger size (200 to 300 of an inch) of the former, the greater thickness of their neurilemma, and a consequent indisposition to the formation of varicose enlargements upon compression. The primitive fibres, or filaments, are assembled into small bundles and enclosed in a distinct sheath, constituting a funiculus; the funiculi are collected into larger bundles or fasciculi, and a single fasciculus or a number of fasciculi connected by fibro-cellular tissue, and invested by a membranous sheath, constitute a nerve. The funiculi, when freshly exposed, present a peculiar zigzag line across their cylinder, which is most probably produced by a wrinkling of the neurilemma, as it is destroyed by making extension upon the nerve.

Communications between nerves take place either by means of the funiculi composing a single nerve, or of the fasciculi in a nervous plexus. In these communications there is no fusion of nervous substance, the cord formed by any two funiculi is constantly enlarged, and corresponds accurately with their combined bulk. Microscopic examination substantiates this observation, and shows that the primitive fibre passes unchanged from one funiculus to the other, so that the primitive fibre is single and uninterrupted from its connection with the cerebro-spinal axis to its terminal distribution. A nervous plexus consists in a communication between the fasciculi and funiculi composing the nerves which are associated in their supply of a limb or of a certain region of the body. During this communication there is an interchange of funiculi, and with the funiculi an interchange of fibres.

The Sympathetic system consists of numerous ganglia, of communicating branches passing between the ganglia, of others passing between the ganglia and the cerebro-spinal axis, and of branches of distribution which are remarkable for their frequent and plexiform communications. The sympathetic nerves also differ from other nerves in their colour, which is of a greyish pearly tint. Examined with the microscope they are seen to be composed of an admixture of grey and white fibres; the white fibres belong to the cerebro-spinal system: the grey are much smaller than the white, less transparent, and the neurilemma is less easily distinguishable from its contents: some of the nerves are composed of grey fibres only, without any admixture of white. The sympathetic ganglia contain the nerve cells observed in the grey substance of the brain; they are firmer in structure and enclosed in a strong investing capsule, the latter being made up of nucleated corpuscles. The fasciculi of fibres entering the ganglion become divided and form a plexus around the globules; they then
converge to constitute one or more fasciculi, by which they quit the ganglion.

The termination of nerves takes place by a separation of the fasciculi into their primitive nervous fibrils, and by the distribution of the latter to the various tissues and surfaces of the body in the form of loops. In the muscles these terminal loops surround the ultimate fasciculi, in the skin they enter into the composition of the papillae, and in very thin membranes they are modified so as to constitute a net-work. The nerves of special sense offer other modifications in the mode of termination of the primitive fibres; thus, in the olfactory nerve, the termination is by loops; in the auditory nerve, partly by loops, and partly by free extremities; and in the optic nerve by free rounded extremities alone.

The capillary vessels of nerves are very minute. They run parallel with the nervous fasciculi, and every here and there are connected by transverse communications, so as to give rise to a net-work composed of oblong meshes very similar to the capillary system of muscles.

The nervous system may be divided for convenience of description into 1. The brain. 2. The spinal cord. 3. The cranial nerves. 4. The spinal nerves. 5. The sympathetic system.

THE BRAIN.

The brain is a collective term which signifies those parts of the nervous system, exclusive of the nerves themselves, which are contained within the cranium; they are the cerebrum, cerebellum, and medulla oblongata. These are invested and protected by the membranes of the brain, and the whole together constitute the encephalon (ἐνσέφαλον, within the head).

MEMBRANES OF THE ENCEPHALON.

Dissection.—To examine the encephalon with its membranes, the upper part of the skull must be removed, by sawing through the external table and breaking the internal table with the chisel and hammer. After the calvarium has been loosened all round, it will require a considerable degree of force to tear the bone away from the dura mater. This adhesion is particularly firm at the sutures, where the dura mater is continuous with a membranous layer interposed between the edges of the bones; in other situations, the connection results from numerous vessels which permeate the inner table of the skull. The adhesion subsisting between the dura mater and bone is greater in the young subject and in old persons than in the adult. Upon being torn away, the internal table will present numerous deeply grooved and ramified channels, corresponding with the branches of the artery meningea media. Along the middle line will be seen a groove
corresponding with the superior longitudinal sinus, and on either side may be frequently observed some depressed fossæ, corresponding with the Pacchionian bodies.

The membranes of the encephalon are the dura mater, arachnoid membrane, and pia mater.

The Dura mater* is the firm, whitish or greyish layer which is brought into view when the calvarium is removed. It is a strong fibrous membrane, somewhat laminated in texture, and composed of white fibrous tissue. Lining the interior of the cranium, it serves as the internal periosteum of that cavity; it is prolonged also into the spinal column, under the name of theca vertebralis, but is not adherent to the bones in that canal as in the cranium. From the internal surface of the dura mater, processes are directed inwards for the support and protection of parts of the brain; while from its exterior, other processes are prolonged outwards to form sheaths for the nerves as they quit the skull and spinal column. Its external surface is rough and fibrous, and corresponds with the internal table of the skull. The internal surface is smooth, and lined by the thin varnish-like lamella of the arachnoid membrane. The latter is a serous membrane. Hence the dura mater becomes a fibro-serous membrane, being composed of its own proper fibrous structure, and the serous layer derived from the arachnoid. There are two other instances of fibro-serous membrane in the body, formed in the same way, namely, the pericardium and túnica albuginea of the testicle.

On the external surface of the dura mater the branches of the middle meningeal artery may be seen ramifying; and in the middle line is a depressed groove, formed by the subsidence of the upper wall of the superior longitudinal sinus. If the sinus be opened along its course, it will be found to be a triangular channel, crossed at its lower angle by numerous white bands, called chordæ Willisii†; granular bodies are also occasionally seen in its interior, these are glandulæ Pacchioni.

The Glandulae Pacchioni‡ are small, round, whitish granulations, occurring singly or in clusters, and forming small groups of various size along the margin of the longitudinal fissure of the hemispheres, but more particularly on the middle of this border. These bodies would seem to be of morbid origin; they are absent in infancy, increase in numbers in adult life, and are abundant in the aged. They are generally associated with opacity of the arachnoid around their bases, but in some instances are wanting even in the adult. They have their point of attachment in the pia mater, from which they seem to spring, carrying with them the arachnoid membrane, and then, in

* So named from a supposition that it was the source of all the fibrous membranes of the body.
† Willis lived in the seventeenth century; he was a great defender of the opinions of Harvey.
‡ These bodies are incorrectly described as conglobate glands by Pacchioni, in an epistolary dissertation, "De Glandulis conglobatis Durse Meningis indeque ortis Lymphaticis ad Piam Matrem productis," published in Rome, in 1705.
proportion to their size, producing various effects upon contiguous parts. For example, when small they remain free or constitute a bond of adhesion between the visceral and parietal layer of the arachnoid; when of larger size they produce absorption of the dura mater, and as the degree of absorption is greater or less, they protrude through that membrane, and form depressions on the inner surface of the cranium, or simply render the dura mater thin and cribriform. Sometimes they cause absorption of the wall of the longitudinal sinus, and projecting into its cavity give rise to the granulations described in relation to that channel.

If the student cut through one side of the dura mater, in the direction of his incision through the skull, and turn it upwards towards the middle line, he will observe the smooth internal surface of this membrane. He will perceive also the large veins of the hemispheres filled with dark blood, and passing from behind forwards to open into the superior longitudinal sinus; and the firm connection, by means of these veins and the Pacchionian bodies, between the opposed surfaces of the arachnoid membrane. If he separate these adhesions with his scalpel, he will see a vertical layer of dura mater descinding between the hemispheres; and if he draw one side of the brain a little onwards, he will be enabled to perceive the extent of the process of membrane, which is called the falx cerebri.

The processes of dura mater which are sent inwards towards the interior of the skull, are the falx cerebri, tentorium cerebelli, and falx cerebelli.

The *Falx cerebri* (falx, a sickle), so named from its sickle-like appearance, narrow in front, broad behind, and forming a sharp curved edge below, is attached in front to the crista galli process of the ethmoid bone, and behind to the tentorium cerebelli.

The *Tentorium cerebelli* (tentorium, a tent) is a roof of dura mater, thrown across the cerebellum and attached at each side to the margin of the petrous portion of the temporal bone; behind to the transverse ridge of the occipital bone, which lodges the lateral sinuses; and to the clinoid processes in front. It supports the posterior lobes of the cerebrum and prevents their pressure* on the cerebellum, leaving only a small opening anteriorly, for the transmission of the crura cerebri.

The *Falx cerebelli* is a small process, generally double, attached to the vertical ridge of the occipital bone beneath the lateral sinus, and to the tentorium. It is received into the indentation between the two hemispheres of the cerebellum.

The layers of the dura mater separate in several situations, so as to form irregular channels which receive the venous blood. These are the *sinuses* of the dura mater, which have been described at page 370.

The student cannot see the tentorium and falx cerebelli until the brain is removed; but he should consider the attachments of the for-

* In leaping animals, as the feline and canine genera, the tentorium forms a bony tent.
mer upon the dried skull, for he will have to incise it in the removal of the brain. He should now proceed to that operation, for which purpose the dura mater is to be incised all round, on a level with the section through the skull, and the scissors are to be carried deeply between the hemispheres of the brain in front, to cut through the anterior part of the falx; then draw the dura mater backwards, and leave it hanging by its attachment to the tentorium. Raise the anterior lobes of the brain carefully with the hand, and lift the olfactory bulbs from the cribiform fossæ with the handle of the scalpel. Then cut across the two optic nerves and internal carotid arteries. Next divide the infundibulum and third nerve, and carry the knife along the margin of the petrous bone at each side, so as to divide the tentorium near its attachment. Cut across the fourth, fifth, sixth, seventh, and eighth nerves in succession with a sharp knife, and pass the scalpel as far down as possible into the vertebral canal, to sever the spinal cord, cutting first to one side and then to the other, in order to divide the vertebral arteries and first cervical nerves. Then let him press the cerebellum gently forwards with the fingers of the right hand, the hemispheres being supported with the left, and the brain will roll into his hand.

The Arteries of the dura mater are the anterior meningeal from the ethmoidal, ophthalmic, and internal carotid. The middle meningeal and meningea parva from the internal maxillary. The inferior meningeal from the ascending pharyngeal and occipital arteries; and the posterior meningeal from the vertebral.

Its Nerves are derived from the nervi molles and vertebral plexus of the sympathetic, from the Casserian ganglion, the ophthalmic nerve, and sometimes from the fourth. The branches from the two last are given off while those nerves are situated by the side of the sella turcica; they are recurrent, and pass backwards between the layers of the tentorium, to the lining membrane of the lateral sinus.

Arachnoid membrane.

The Arachnoid (ἀράχνην σίδος, like a spider's web), so named from its extreme tenuity, is the serous membrane of the cerebro-spinal centre, and, like other serous membranes, a shut sac. It envelopes the brain and spinal cord (visceral layer) and is reflected upon the inner surface of the dura mater (parietal layer), giving to that membrane its serous investment.

On the upper surface of the hemispheres the arachnoid is transparent, but may be demonstrated as it passes across the sulci from one convolution to another by injecting, with a blow-pipe, a stream of air beneath it. At the base of the brain the membrane is opalescent and thicker than in other situations, and more easily demonstrable from the circumstance of stretching across the interval between the middle lobes of the hemispheres. The space which is included between this
layer of membrane and those parts of the base of the brain which are bounded by the optic commissure and fissures of Sylvius in front, and the pons Varolii behind, is termed the *anterior subarachnoidean space*. Another space formed in a similar manner, between the under part of the cerebellum and the medulla oblongata, is the *posterior sub-arachnoidean space*; and a third space, situated upon the corpora quadrigemina, may be termed the *superior sub-arachnoidean space*. These spaces communicate freely with each other, the anterior and posterior across the crura cerebelli, the anterior and the middle around the crura cerebri, and the latter and the posterior across the cerebellum in the course of the vermiform processes. They communicate also with a still larger space formed by the loose disposition of the arachnoid around the spinal cord, the *spinal sub-arachnoidean space*. The whole of these spaces, with the slighter spaces between the convolutions of the hemispheres, constitute one large and continuous cavity which is filled with a limpid, serous secretion, the *sub-arachnoidean fluid*,* a fluid which is necessary to the maintenance and protection of the cerebro-spinal mass. The quantity of the sub-arachnoidean fluid is determined by the relative size of the cerebro-spinal axis and that of the containing cavity, and is consequently very variable. It is smaller in youth than in old age, and in the adult has been estimated at about two ounces. The visceral layer of the arachnoid is connected to the pia mater by a delicate areolar tissue, which in the sub-arachnoidean spaces is loose and filamentous. The serous secretion of the true cavity of the arachnoid is very small in quantity as compared with the sub-arachnoidean fluid.

The arachnoid does not enter into the ventricles of the brain, as imagined by Bichât, but is reflected inwards upon the venæ Galeni for a short distance only, and returns upon those vessels to the dura mater of the tentorium. It surrounds the nerves as they originate from the brain, and forms a sheath around them to their point of exit from the skull. It is then reflected back upon the inner surface of the dura mater.

There are no vessels apparent in the arachnoid, and no nerves have been traced into it.

**Pia mater.**

The *Pia mater* is a vascular membrane composed of innumerable vessels held together by a thin layer of fibro-cellular tissue. It invests the whole surface of the brain, dipping into the sulci between the convolutions, and forming a fold in its interior called *velum interpositum*. It also forms folds in other situations, as in the third and fourth ventricles, and in the longitudinal grooves of the spinal cord.

* The presence of a serous fluid beneath the arachnoid has given rise to the conjecture that a sub-arachnoid serous membrane may exist in that situation. Such a supposition is quite unnecessary to explain the production of the secretion, since the pia mater is fully adequate to that function.
This membrane differs very strikingly in its structure in different parts of the cerebro-spinal axis. Thus, on the surface of the cerebrum, in contact with the soft grey matter of the brain, it is excessively vascular, forming remarkable loops of anastomoses in the interspaces of the convolutions, and distributing multitudes of minute straight vessels to the grey substance. In the substantia perforata, again, and locus perforatus, it gives off tufts of small arteries, which pierce the white matter to reach the grey substance in the interior. But upon the crura cerebri, pons Varolii, and spinal cord, its vascular character seems almost lost. It has become a dense fibrous membrane, difficult to tear off, and forming the proper sheath of the spinal cord.

The pia mater is the nutrient membrane of the brain, and derives its blood from the internal carotid and vertebral arteries.

Its Nerves are the minute filaments of the sympathetic, which accompany the branches of the arteries.

The Cerebrum is divided superiorly into two hemispheres by the great longitudinal fissure, which lodges the falx cerebri, and marks the original development of the brain by two symmetrical halves.

Each hemisphere, upon its under surface, admits of a division into three lobes, anterior, middle, and posterior. The anterior lobe rests upon the roof of the orbit, and is separated from the middle by the fissure of Sylvius.* The middle lobe is received into the middle fossa of the base of the skull, and is separated from the posterior by a slight impression produced by the ridge of the petrous bone. The posterior lobe is supported by the tentorium.

If the upper part of one hemisphere, at about one-third from its summit, be removed with a scalpel, a centre of white substance will be observed, surrounded by a narrow border of grey, which follows the line of the sulci and convolutions, and presents a zigzag form. This section from exhibiting the largest surface of medullary substance demonstrable in a single hemisphere is called centrum ovale minus; it is spotted by numerous small red points (puncta vasculosa) which are produced by the escape of blood from the cut ends of minute arteries and veins.

Now separate carefully the two hemispheres of the cerebrum, and a broad band of white substance (corpus callosum) will be seen to connect them; it will be seen also that the surface of the hemisphere where it comes into contact with the corpus callosum is bounded by a large convolution (gyrus fornicatus) which lies horizontally on that body, and may be traced forwards and backwards to the base of the

* James Dubois, a celebrated professor of anatomy in Paris, where he succeeded Vidius in 1550, although known much earlier by his works and discoveries, but particularly by his violence in the defence of Galen. His name was Latinised to Jacobus Sylvius.
brain, terminating by each extremity at the fissure of Sylvius. The sulcus between this convolution and the corpus callosum has been termed, very improperly, the "ventricle of the corpus callosum," and some longitudinal fibres (striae longitudinales laterales), which are brought into view when the convolution is raised, were called by Reil the "covered band." If, now, the upper part of each hemisphere be removed to a level with the corpus callosum, a large expanse of medullary substance, surrounded by a zigzag line of grey substance corresponding with the convolutions and sulci of the two hemispheres, will be seen; this is the centrum ovale majus of Vieussens.

The Corpus callosum (callosus, hard) is a thick layer of medullary fibres passing transversely between the two hemispheres, and constituting their great commissure. It is situated in the middle line of the centrum ovale majus, but nearer to the anterior than to the posterior part of the brain, and terminates anteriorly in a rounded border (genu), which may be traced downwards to the base of the brain in front of the commissure of the optic nerves. Posteriorly it forms a thick rounded fold (splenium), which is continuous with the fornix. The breadth of the corpus callosum is about four inches.

Beneath the posterior rounded border of the corpus callosum is the transverse fissure of the cerebrum, which extends between the hemispheres and crura cerebri from very near the fissure of Sylvius on one side, to the same point on the opposite side of the brain. It is through this fissure that the pia mater communicates with the velum interpositum. And it was here that Bichat conceived the arachnoid to enter the ventricles; hence it is also named the fissure of Bichat.

Along the middle line of the corpus callosum is the raphé, a linear depression between two slightly elevated longitudinal bands (chorde longitudinales Lancisii); and, on either side of the raphé, may be seen the linea transversa, which mark the direction of the fibres of which the corpus callosum is composed. These fibres may be traced into the hemispheres on either side, and they will be seen to be crossed at about an inch from the raphé by the longitudinal fibres of the covered band of Reil. Anteriorly and posteriorly the fibres of the corpus callosum curve into their corresponding lobe.

If, now, a superficial incision be made through the corpus callosum on either side of the raphé, two irregular cavities will be opened, which extend from one extremity of the hemispheres to the other: these are the lateral ventricles. To expose them completely, their upper boundary should be removed with the scissors. In making this dissection the thin and diaphanous membrane of the ventricles may frequently be seen.

LATERAL VENTRICLES.—Each lateral ventricle is divided into a central cavity, and three smaller cavities called cornua. The anterior cornu curves forwards and outwards in the anterior lobe; the middle cornu descends into the middle lobe; and the posterior cornu passes backwards in the posterior lobe, converging towards its fellow of the opposite side. The central cavity is triangular in its form, being
bounded above (*roof*) by the corpus callosum; internally by the septum lucidum, which separates it from the opposite ventricle; and

Fig. 139.*

* The lateral ventricles of the cerebrum. 1, 1. The two hemispheres cut down to a level with the corpus callosum so as to constitute the centrum ovale majus. The surface is seen to be studded with the small vascular points—puncta vasculosa; and surrounded by a narrow margin which represents the grey substance. 2. A small portion of the anterior extremity (genu) of the corpus callosum. 3. Its posterior boundary (splenium); the intermediate portion forming the roof of the lateral ventricles has been removed so as to completely expose those cavities. 4. A part of the septum lucidum, shewing an interspace between its layers—the fifth ventricle. 5. The anterior cornu of one side. 6. The commencement of the middle cornu. 7. The posterior cornu. 8. The corpus striatum of one ventricle. 9. The tenia semicircularis covered by the vena corporis striati and tenia Tarini. 10. A small part of the thalamus opticus. 11. The dark fringe-like body to the left of the numeral is the choroid plexus. This plexus communicates with that of the opposite ventricle through the foramen of Monro, or foramen commune anterius; a bristle is passed through this opening, and its extremities are seen resting on the corpus striatum at each side. The figure 11 rests upon the edge of the fornix, upon that part of it which is called the corpus fimbriatum. 12. The fornix. 13. The commencement of the hippocampus major descending into the middle cornu. The rounded oblong body in the posterior cornu of the lateral ventricle, directly behind the figure 13, is the hippocampus minor.
below (floor) by the following parts, taken in their order of position from before backwards:—

Corpus striatum,
Tenia semicircularis,
Thalamus opticus,
Choroid plexus,
Corpus fimbriatum,
Fornix.

The Corpus striatum is named from the striated lines of white and grey matter which are seen upon cutting into its substance. It is grey on the exterior, and of a pyriform shape. The broad end, directed forwards, rests against the corpus striatum of the opposite side: the small end, backwards, is separated from its fellow by the interposition of the thalami optici. The corpora striata are the superior ganglia of the cerebrum.

The Tenia semicircularis (tenia, a fillet) is a narrow band of medulary substance, extending along the posterior border of the corpus striatum, and serving as a bond of connection between that body and the thalamus opticus. The tenia is partly concealed by a large vein (vena corporis striati), formed by small vessels from the corpus striatum and thalamus opticus, which terminates in the vena Galeni of its own side. The vein is overlaid by a yellowish band, a thickening of the lining membrane of the ventricle. This was first noticed and described by Tarinus, under the name of the horny band. We may therefore term it, tenia Tarini.*

The Thalamus opticus (thalamus, a bed) is an oblong body, having a thin coating of white substance on its surface; it has received its name from giving origin to one root of the optic nerve. It is the inferior ganglion of the cerebrum. Part only of the thalamus is seen in the floor of the lateral ventricle; we must, therefore, defer its further description until we can examine it in its entire extent.

The Choroid plexus (κόρων, νήσος, resembling the chorion†) is a vascular fringe extending obliquely across the floor of the lateral ventricle, and sinking into the middle cornu. Anteriorly, it is small and tapering, and communicates with the choroid plexus of the opposite ventricle, through a large oval opening, the foramen of Monro, or foramen commune anterius. This foramen may be distinctly seen by pulling slightly on the plexus, and pressing aside the septum lucidum with the handle of the knife. It is situated between the under surface of the fornix, and the anterior extremities of the thalami optici, and forms a communication transversely between the lateral ventricles, and perpendicularly with the third ventricle.

* Peter Tarin, a French anatomist: his work, entitled "Adversaria Anatomica," was published in 1750.
† See the note appended to the description of the choroid coat of the eyeball.
The choroid plexus presents upon the surface a number of minute vascular processes, which are termed villi. They are invested by a very delicate epithelium, surmounted by cilia, which have been seen in active movement in the embryo. In their interior the plexuses not unfrequently contain particles of calcareous matter, and they are sometimes covered by small clusters of serous cysts.

The Corpus fimbriatum is a narrow white band, which is situated immediately behind the choroid plexus, and extends with it into the descending cornu of the lateral ventricle. It is in fact the lateral thin edge of the fornix, and being attached to the hippocampus major in the descending horn of the lateral ventricle, is also termed, tenia hippocampi.

The Fornix is a white layer of medullary substance, of which a portion only is seen in this view of the ventricle.

The Anterior cornu is triangular in its form, sweeping outwards, and terminating by a point in the anterior lobe of the brain, at a short distance from its surface.

The Posterior cornu or digital cavity curves inwards, as it extends back into the posterior lobe of the brain, and likewise terminates near the surface. An elevation corresponding with a deep sulcus between two convolutions projects into the area of this cornu, and is called the hippocampus minor.

The Middle or descending cornu, in descending into the middle lobe of the brain, forms a very considerable curve, and alters its direction several times as it proceeds. Hence it is described as passing backwards and outwards and downwards, and then turning forwards and inwards. This complex expression of a very simple curve has given birth to a symbol formed by the primary letters of these various terms; and by means of this the student recollects with ease the course of the cornu, BODPI. It is the largest of the three cornua, and terminates close to the fissure of Sylvius, after having curved around the crus cerebri.

The middle cornu should now be laid open, by inserting the little finger into its cavity, and making it serve as a director for the scalpel in cutting away the side of the hemisphere, so as to expose it completely.

The Superior boundary of the middle cornu is formed by the under surface of the thalamus opticus, upon which are the two projections called corpus geniculatum internum and externum; and the inferior wall by the various parts which are often spoken of as the contents of the middle cornu: these are the—

- Hippocampus major,
- Pes hippocampi,
- Pes accessorius,
- Corpus fimbriatum,
- Choroid plexus,
- Fascia dentata,*
- Transverse fissure.
The Hippocampus major or cornu Ammonis, so called from its resemblance to a ram's horn, the famous crest of Jupiter Ammon, is a considerable projection from the inferior wall, and extends the whole length of the middle cornu. Its extremity is likened to the foot of an animal, from its presenting a number of knuckle-like elevations upon the surface, and is named pes hippocampi. The hippocampus major is the internal surface of the convolution ( gyrus forningatus) of the lateral edge of the hemisphere, the convolution which has been previously described as lying upon the corpus callosum and extending downwards to the base of the brain to terminate at the fissure of Sylvius. If it be cut across, the section will be seen to resemble the extremity of a convoluted scroll, consisting of alternate layers of white and grey substance. The hippocampus major is continuous superiority with the fornix and corpus callosum, deriving from the latter its medullary layer.

The Pes accessorius is a swelling somewhat resembling the hippocampus major, but smaller in size; it is situated on the outer wall of the cornu, and is frequently absent.

The Corpus fimbriatum (tenia hippocampi) is the narrow white band which is prolonged from the central cavity of the ventricle, and is attached along the inner border of the hippocampus major. It is lost inferiorly on the hippocampus.

Fascia dentata:—if the corpus fimbriatum be carefully raised, a narrow serrated band of grey substance, the margin of the grey substance of the middle lobe, will be seen beneath it; this is the fascia dentata. Beneath the corpus fimbriatum will be likewise seen the transverse fissure of the brain, which has been before described as extending from near the fissure of Sylvius on one side, across to the same point on the opposite side of the brain. It is through this fissure that the pia mater communicates with the choroid plexus, and the latter obtains its supply of blood. The fissure is bounded on one side by the corpus fimbriatum, and on the other by the under surface of the thalamus opticus.

The internal boundary of the lateral ventricle is the septum lucidum. This septum is thin and semi-transparent, and consists of two laminae of cerebral substance attached above to the under surface of the corpus callosum at its anterior part, and below to the fornix. Between the two layers is a narrow space, the fifth ventricle, which is lined by a proper membrane. The fifth ventricle may be shown, by snipping through the septum lucidum transversely with the scissors.

The corpus callosum should now be cut cross towards its anterior extremity, and the two ends carefully dissected away. The anterior portion will be retained only by the septum lucidum, but the posterior will be found incorporated with the white layer beneath, which is the fornix.

Fornix.—The fornix (arch) is a triangular lamina of white substance, broad behind, and extending into each lateral ventricle: narrow in front, where it terminates in two crura, which arch downwards to
the base of the brain. The two crura descend in a curved direction to
the base of the brain, embedded in grey substance in the lateral walls
of the third ventricle, and lying directly behind the anterior commis-
sure. At the base of the brain they make a sudden curve upon them-
selves and constitute the corpora albicantia, from which they may be
traced upwards to their origin in the thalami optici. Opening trans-
versely beneath these two crura, just as they are about to arch down-
wards, is the foramen of communication between the lateral and the
third ventricles, the foramen of Monro; or, foramen commune anterius.

Fig. 140.*

* The mesial surface of a longitudinal section of the brain. The incision has
been carried along the middle line; between the two hemispheres of the cere-
brum, and through the middle of the cerebellum and medulla oblongata. 1.
The inner surface of the left hemisphere. 2. The divided surface of the cere-
bellum, shewing the arbor vitae. 3. The medulla oblongata. 4. The corpus
calosum, curving downwards in front to terminate at the base of the brain;
and rounded behind, to become continuous with 5, the fornix. 6. One of the
crura of the fornix descending to 7, one of the corpora albicantia. 8. The sep-
tum lucidum. 9. The velum interpositum, communicating with the pia mater
of the convolutions through the fissure of Bichât. 10. Section of the middle
commissure situated in the third ventricle. 11. Section of the anterior com-
missure. 12. Section of the posterior commissure; the commissure is some-
what above and to the left of the numeral. The interspace between 10 and 11
is the foramen commune anterius, in which the crus of the fornix (6) is situ-
ated. The interspace between 10 and 12 is the foramen commune posterius.
13. The corpora quadrigemina, upon which is seen resting the pineal gland, 14.
15. The iter a tertio ad quartum ventriculum, or aqueduct of Sylvius. 16. The
fourth ventricle. 17. The pons Varolii, through which are seen passing the
diverging fibres of the corpora pyramidalia. 18. The crus cerebri of the left
side, with the third nerve arising from it. 19. The tuber cinereum, from
which projects the infundibulum having the pituitary gland appended to its
extremity. 20. One of the optic nerves. 21. The left olfactory nerve termi-
nating anteriorly in a rounded bulb.
The choroid plexuses communicate, and the veins of the corpora striata pass through this opening. The lateral thin edges of the fornix are continuous posteriorly with the concave border of the hippocampus major at each side, and form the narrow white band called corpus fimbriatum (posterior crus of the fornix). In the middle line the fornix is continuous with the corpus callosum, and at each side with the hippocampus major and minor. Upon the under surface of the fornix towards its posterior part, some transverse lines are seen passing between the diverging corpora fimbriata: this appearance is termed the lyra (corpus psalloides), from a fancied resemblance to the strings of a harp.

The fornix may now be removed by dividing it across anteriorly, and turning it backwards, at the same time separating its lateral connections with the hippocampi. If the student examine its under surface, he will perceive the lyra above described.

Beneath the fornix is the velum interpositum, a duplication of pia mater introduced into the interior of the brain, through the transverse fissure. The velum is continuous at each side with the choroid plexus, and contains in its inferior layer, two large veins (the vena Galeni) which receive the blood from the corpora striata and choroid plexuses, and terminate posteriorly, after uniting into a single trunk, in the straight sinus. Upon the under surface of the velum interpositum are two fringe-like bodies, which project into the third ventricle. These are the choroid plexuses of the third ventricle; posteriorly these fringes enclose the pineal gland.

If the velum interpositum be raised and turned back, an operation which must be conducted with care, particularly at its posterior part where it invests the pineal gland, the thalami optici and the cavity of the third ventricle will be brought into view.

**THALAMI OPTICI.**—The thalami optici are two oblong, square-shaped bodies, of a white colour superficially, inserted between the two diverging portions of the corpora striata. In the middle line a fissure exists between them, which is called the third ventricle. Posteriorly and inferiorly, they form the superior wall of the descending cornu, and present two rounded elevations called corpus geniculatum externum and internum. The corpus geniculatum externum is the larger of the two, and of a greyish colour; it is the principal origin of the optic nerve. Anteriorly, the thalami are connected with the corpora albicantia by means of two white bands, which appear to originate in the white substance uniting the thalami to the corpora striata. Externally they are in relation with the corpora striata and hemispheres. In their interior the thalami are composed of white fibres mixed with grey substance. They are essentially the inferior ganglia of the cerebrum.

**THIRD VENTRICLE.**—The third ventricle is the fissure between the two thalami optici. It is bounded above by the under surface of the velum interpositum, from which are suspended the choroid plexuses of the third ventricle. Its floor is formed by the grey substance of the anterior termination of the corpus callosum, called lamina cinerea,
the tuber cinereum, corpora albicantia, and locus perforatus. Laterally it is bounded by the thalami optici; anteriorly by the anterior commissure and crura of the fornix; and posteriorly by the posterior commissure and the iter a tertio ad quartum ventriculum. The third ventricle is crossed by three commissures, the anterior, middle, and posterior; and between these are two spaces, called foramen commune anterius and foramen commune posterius.

The Anterior commissure is a small rounded white cord, which enters the corpus striatum at either side, and spreads out in the substance of the hemispheres; the middle, or soft commissure consists of grey matter, which is continuous with the grey lining of the ventricle, it connects the adjacent sides of the thalami optici; the posterior commissure, smaller than the anterior, is a rounded white cord, connecting the two thalami optici posteriorly.

The space between the anterior and middle commissure is called the foramen commune anterius, and is that to which Monro has given his name (foramen of Monro). It is the medium of communication between the lateral and third ventricles and it transmits superiorly the choroid plexus and the venæ corporum striatorum. The foramen commune anterius is also termed, iter ad infundibulum, from leading downwards to the funnel-shaped cavity of the infundibulum. The crura of the fornix are embedded in the lateral walls of the foramen commune, and are concealed from view in this situation by the layer of grey substance which lines the interior of the third ventricle. If the crura be slightly separated, the anterior commissure will be seen crossing from one corpus striatum to the other, immediately in front of them. The space between the middle and posterior commissure is the foramen commune posterius; it is much shallower than the preceding, and is the origin of a canal, the aqueduct of Sylvius or iter a tertio ad quartum ventriculum, which leads backwards beneath the posterior commissure and through the base of the corpora quadrigemina to the upper part of the fourth ventricle.

Corpora quadrigemina.—The corpora quadrigemina, or optic lobes, are situated immediately behind the third ventricle and posterior commissure; and beneath the posterior border of the corpus callosum. They form, indeed, at this point, the inferior boundary of the transverse fissure of the hemispheres, the fissure of Bichat. The anterior pair of these bodies are grey in colour, and are named nates: the posterior pair are white and much smaller than the anterior; they are termed testes. From the nates may be traced a rounded process (brachium anterius) which passes obliquely outwards into the thalamus opticus; and from the testes a similar but smaller process (brachium posterius) which has the same destination. The corpus geniculatum internum lies in the interval of these two processes where they enter the thalamus, and behind the brachium posterius is a prominent band (laqueus) which marks the course of the superior division of the fasciculus olivaris. The corpora quadrigemina are perforated longitudinally through their base by the aqueduct of Sylvius; they are
covered in partly by the pia mater and partly by the velum interpositum, and the nates form the base of support of the pineal gland.

**Pineal Gland.**—The pineal gland is a small reddish grey body of a conical form (hence its synonym cernarum), situated on the anterior part of the nates and invested by a duplicature of pia mater derived from the under part of the velum interpositum. The pineal gland, when pressed between the fingers is found to contain a gritty matter (acervulus) composed chemically of phosphate and carbonate of lime and is sometimes hollow in the interior. It is connected to the brain by means of two medullary cords called peduncles and a thin lamina derived from the posterior commissure; the peduncles of the pineal gland are attached to the thalami optici and may be traced along the upper and inner margin of those bodies to the crura of the fornix with which they become blended. From the close connection subsisting between the pia mater and the pineal gland and the softness of texture of the latter, the gland is liable to be torn away in the removal of the pia mater.

Behind the corpora quadrigemina is the cerebellum, and beneath the cerebellum the fourth ventricle. The student must therefore divide the cerebellum down to the fourth ventricle, and turn its lobes aside to examine that cavity.

**Fourth Ventricle.**—The fourth ventricle (sinus rhomboidalis) is the ventricle of the medulla oblongata, upon the posterior surface of which, and of the pons Varolii, it is placed. It is a lozenge-shaped cavity, bounded on each side by a thick cord passing between the cerebellum and corpora quadrigemina, called the processus cerebello ad testes, and by the corpus restiforme. It is covered in behind by the cerebellum, and by a thin lamella of medullary substance, stretched between the two processus cerebello ad testes, termed the value of Vieussens.*

That portion of the cerebellum which forms the posterior boundary of the fourth ventricle, presents four small prominences or lobules, and a thin layer of medullary substance, the velum medullare posterius. Of the lobules two are placed in the middle line, the nodulus and uvula, the former being before the latter; the remaining two are named amygdulae, or tonsils, and are situated one on either side of the uvula. They all project into the cavity of the fourth ventricle, and the velum medullare posterius is situated in front of them. The value of Vieussens or velum medullare anterius is an extremely thin lamella of medullary substance, prolonged from the white matter of the cerebellum to the testes, and attached on each side to the processus cerebello ad testes. This lamella is overlaid for a short distance by a thin, transversely-grooved lobule of grey substance (linguette laminosa) derived from the anterior border of the cerebellum, and its junction with the testes is strengthened by a narrow slip given off by the commissure of those bodies, the frenulum veli medullaris anterioris. The anterior wall, or

* Raymond Vieussens, a great discoverer in the anatomy of the brain and nervous system. His "Neurographia Universalis" was published at Lyons, in 1685.
floor of the fourth ventricle is formed by two slightly convex bodies, processus teretes or posterior pyramids, separated by a longitudinal groove which is continuous inferiorly with the sulcus longitudinalis posterior of the spinal cord. The processus teretes are crossed transversely by several white and grey fasciculi (lineæ transverse) the origin of the auditory nerves. And upon the lower part of the floor of this ventricle is an impression resembling the point of a pen and hence named calamus scriptorius; the lateral boundaries of the calamus are the processus clavati of the posterior median columns of the spinal cord. Above, the fourth ventricle is bounded by the corpora quadrigemina and aqueduct of Sylvius; and below by a layer of pia mater and arachnoid, called the valve of the arachnoid. It is by rupture of this latter that a communication is established between the ventricles of the brain and the sub-arachnoidean space. Within the fourth ventricle and lying against the uvula and tonsils are two small vascular fringes formed by the pia mater, the choroid plexuses of the fourth ventricle. The fourth ventricle is lined by grey matter derived from the interior of the spinal cord, the grey matter being partly concealed by a thin expansion of white substance.

LINING MEMBRANE OF THE VENTRICLES.

The lining membrane of the ventricles is a serous layer distinct from the arachnoid; it lines the whole of the interior of the lateral ventricles, and is connected above and below with the attached border of the choroid plexus, so as to exclude all communication between the ventricles and the exterior of the brain. From the lateral ventricles it is reflected through the foramen of Monro on each side, into the third ventricle, which it invests throughout. From the third it is conducted into the fourth ventricle, through the iter a tertio ad quartum ventriculum, and lines its interior, together with the layer of pia mater which forms its inferior boundary. In this manner a perfect communication is established between all the ventricles, with the exception of the fifth, which has its own proper membrane. It is this membrane which gives them their polished surface, and transudes the secretion which moistens their interior. When the fluid accumulates to an unnatural degree, it may then break down this layer and the layer of pia mater at the bottom of the fourth ventricle, and thus make its way into the sub-arachnoidean space; but in the normal condition it is doubtful whether a communication exists between the interior of the ventricles and the serous cavity of the sub-arachnoidean space.

CEREBELLUM.

The Cerebellum, seven times smaller than the cerebrum, is situated beneath the posterior lobes of the latter, being lodged in the posterior fossa of the base of the cranium and protected from the superincum-
bent pressure of the cerebrum by the tentorium cerebelli. Like the cerebrum, it is composed of grey and white substance, the former occupying the surface, the latter the interior, and its surface is formed of parallel lamellae separated by sulci, and here and there by deeper sulci. In form, the cerebellum is oblong and flattened, its greater diameter being from side to side, its two surfaces looking upwards and downwards, and its borders being anterior, posterior, and lateral. In consideration of its shape the cerebellum admits of a division into two hemispheres, into certain processes termed processes and lobules, and into certain divisions of its substance called lobes, formed upon the hemispheres by the deeper sulci above referred to. The two hemispheres are separated from each other on the upper surface of the cerebellum by a longitudinal ridge which is termed the superior vermiform process and which forms a commissure between them. On the anterior border of the organ there is a semi-lunar notch, incisura cerebelli anterior, which encircles the corpora quadrigemina posteriorly. On the posterior border there is another notch, incisura cerebelli posterior, which receives the upper part of the falx cerebelli; and upon the under surface is a deep fissure corresponding with the medulla oblongata, and termed the vallecula (valley).

Each hemisphere of the cerebellum is divided by means of a fissure (sulcus horizontalis) which runs along its free border, into an upper and a lower portion, and upon each of these portions certain lobes are marked out. Thus on the upper portion there are two such lobes separated by a sulcus, somewhat more strongly marked than the rest, and extending deeper into the substance of the cerebrum; they are the lobus superior anterior and lobus superior posterior. Upon the under portion of the hemisphere there are three such lobes, namely, lobus inferior anterior, medius, and posterior, and two additional ones of peculiar form, the lobus inferior internus or tonsil, and the flocculus. The tonsil (amygdala), is situated on the side of the vallecula and projects into the fourth ventricle. The flocculus or pneumogastric lobule, long and slender, extends from the side of the vallecula around the corpus restiforme to the crus cerebelli, lying behind the filaments of the eighth pair of nerves.

The commissure between the two hemispheres is termed the worm (vermis); that portion of the worm which occupies the upper surface of the cerebellum as far back as the horizontal fissure, being the processus vermiformis superior, and that which is lodged within the vallecula being the processus vermiformis inferior. The superior vermiform process is a prominent longitudinal ridge, extending from the incisura anterior to the incisura posterior cerebelli. In imitation of the hemispheres it is divided into lobes of which three have received names namely, the lobulus centralis, which is a small lobe situated in the incisura anterior; the monticulus cerebelli, a longer lobe, having its peak and declivity; and a small lobe near the incisura posterior, the commissura simplex. The lobes of the inferior vermiform process are four in number, namely,—the commissura brevis, situated in the incisura
posterior, below the horizontal fissure; the pyramid, a small, obtusely-pointed eminence; a larger prominence, the uvula, situated between the tonsils, and connected with them by means of a commissure; and in front of the uvula, the nodulus. In front of the nodulus is a thin lamina of medullary substance, consisting of a central and two lateral portions, the velum medullare posterius (valvula Tarini), and between this velum in front, and the nodulus and uvula behind, is a deep fossa which is known as the swallow’s nest (nidus hirundinis). The velum medullare anterius is the valve of Vieussens, described with the fourth ventricle; both these vela proceed from the same point in the roof of that ventricle and separate from each other at an angle, the one passing obliquely forwards, the other obliquely backwards.

When a vertical incision is made into the cerebellum that appearance is seen which has been denominated arbor vitae cerebelli; the white substance in the centre of such a section resembles the trunk of a tree from which branches are given off, and from the branches branchlets and leaves, the two latter being coated by a moderately thick and uniform layer of grey substance. If the incision be made somewhat nearer to the commissure than to the lateral border of the organ, a yellowish grey dentated line enclosing medullary substance, traversed by the openings of numerous vessels, will be seen in the centre of the white substance. This is the ganglion of the cerebellum, the corpus rhomboideum or dentatum, from which the peduncles of the cerebellum proceed. The grey line is dense and horny in structure, and is the cut edge of a thin capsule, open towards the medulla oblongata.

The cerebellum is associated with the rest of the encephalon by means of three pairs of rounded cords or peduncles, superior, middle, and inferior. The superior peduncles, or processus e cerebello ad testes, proceed from the cerebellum forwards and upwards to the testes, in which they are lost. They form the anterior part of the lateral boundaries of the fourth ventricle and give attachment by their inner borders to the valve of Vieussens which is stretched between them. At their junction with the testes they are crossed by the fourth pair of nerves. The middle peduncles, or crura cerebelli ad pontem, the largest of the three, issue from the cerebellum through the anterior extremity of the sulcus horizontalis, and are lost in the pons Varolii. The inferior peduncles, or crura ad medullam oblongatam, are the corpora restiformia which descend to the posterior part of the medulla oblongata, and form the inferior portion of the lateral boundaries of the fourth ventricle.

The student should now prepare to study the base of the brain: for this purpose the organ should be turned upon its incised surface; and if the dissection have hitherto been conducted with care, he will find the base perfectly uninjured. The arachnoid membrane, some parts
of the pia mater, and the circle of Willis, must be carefully cleared away in order to expose all the parts to be examined. These he will find arranged in the following order from before backwards:

- Longitudinal fissure,
- Olfactory nerves,
- Fissure of Sylvius,
- Substantia perforata,
- Commencement of the transverse fissure,
- Optic commissure,
- Tuber cinereum,
- Infundibulum,
- Corpora albicantia,
- Locus perforatus,
- Crura cerebri,
- Pons Varolii,
- Crura cerebelli,
- Medulla oblongata.

The Longitudinal fissure is the space separating the two hemispheres; it is continued downwards to the base of the brain, and divides the two anterior lobes. In this fissure the anterior cerebral arteries ascend towards the corpus callosum; and, if the two lobes be slightly drawn asunder, the anterior border (genu) of the corpus callosum will be seen descending to the base of the brain. Arrived at the base of the brain, the corpus callosum terminates by a concave border which is prolonged to the commissure of the optic nerves by a thin layer of grey substance, the lamina cinerea. The lamina cinerea is the anterior part of the inferior boundary of the third ventricle. On each side of the lamina cinerea the corpus callosum is continued into the substantia perforata and crura cerebri, and upon the latter forms a narrow medullary band lying externally to, and slightly overlapping the optic tract, the medulla innominata.

Upon the under surface of each anterior lobe, on either side of the longitudinal fissure, is the olfactory nerve, with its bulb.

The Fissure of Sylvius bounds the anterior lobe posteriorly, and separates it from the middle lobe; it lodges the middle cerebral artery. If this fissure be followed outwards, a small isolated cluster of five or six convolutions will be observed; these constitute the island of Reil. The island of Reil, together with the substantia perforata, form the base of the corpus striatum.

The Substantia perforata is a triangular plane of white substance, situated at the inner extremity of the fissure of Sylvius. It is named perforata, from being pierced by a number of openings for small arteries, which enter the brain in this situation to supply the grey substance of the corpus striatum.

Passing backwards on each side beneath the edge of the middle lobe, is the commencement of the great transverse fissure, which extends beneath the hemisphere of one side to the same point on the op-
posite side. A probe passed into this fissure between the crus cerebri and middle lobe would enter the middle cornu of the lateral ventricle.

The Optic commissure is situated on the middle line; it is the point of communication between the two optic nerves.

The Tuber cinereum is an eminence of grey substance situated immediately behind the optic commissure, and in front of the corpora mammillaria. From its centre there projects a small conical body of grey substance, apparently a prolongation of the tuber cinereum, the infundibulum. The infundibulum is hollow in its interior, enclosing a short cecal canal, which communicates with the cavity of the third ventricle, and below the termination of the canal the conical process becomes connected with the pituitary gland. The infundibulum and tuber cinereum form part of the floor of the third ventricle.

The Pituitary gland (hypophysis cerebri), is a small, flattened, reddish-grey body situated in the sella turcica, and closely retained in that situation by the dura mater and arachnoid. It consists of two lobes, closely pressed together, the anterior lobe being the larger of the two and oblong in shape, the posterior round. Both lobes are connected with the infundibulum, but the latter is so soft in texture as to be generally torn through in the removal of the brain. Indeed, for the purposes of the student, it is better to effect this separation with the knife, and leave the pituitary body in situ, to be examined with the base of the cranium.

The Corpora albicantia (mammillaria, pisiformia, bulbi fornicis), are two white convex bodies, having the shape and size of peas, situated behind the tuber cinereum, and between the crura cerebri. They are a part of the crura of the fornix, which after their origin from the thalami optici descend to the base of the brain, and making a sudden curve upon themselves previously to their ascent to the lateral ventricles constitute the corpora albicantia. When divided by section, these bodies will be found to be composed of a capsule of white substance, containing grey matter, the grey matter of the two corpora being connected by means of a commissure.

The Locus perforatus is a layer of whitish grey substance, connected in front with the corpora albicantia, behind with the pons Varolii, and on each side with the crura cerebri, between which it is situated. It is perforated by several thick tufts of arteries, which are distributed to the thalami optici and third ventricle, of which it assists in forming the floor. It is sometimes called the pons Tarini.

The Crura cerebri are two thick white cords which issue from the anterior border of the pons Varolii, and diverge to each side to enter the thalami optici. By their outer side the crura cerebri are continuous with the corpora quadrigemina, and above they constitute the lower boundary of the aqueduct of Sylvius. In their interior they contain grey matter, which has a semilunar shape when the crus is divided transversely, and has been termed the locus niger. The third nerve will be observed to arise from the inner side of each, and the fourth nerves wind around their outer border from above.
The *Pons Varolii* (protuberantia annularis, nodus encephali), is the broad transverse band of white fibres which arches like a bridge.

Fig. 141.

* Constant Varolius, Professor of Anatomy in Bologna; died in 1578. He dissected the brain in the course of its fibres, beginning from the medulla oblongata; a plan which has since been perfected by Vieuusses, and by Gall and Spurzheim. The work containing his mode of dissection, "De Resolucione Corporis Humani," was published after his death, in 1591.

† The under surface or base of the brain. 1. The anterior lobe of one hemisphere of the cerebrum. 2. The middle lobe. 3. The posterior lobe almost concealed by (4) the hemisphere of the cerebellum. 5. The pyramidal lobe of the inferior veriform process of the cerebellum. 6. The pneumogastric lobule. 7. The longitudinal fissure. 8. The olfactory nerves, with their bulbous expansions. 9. The substantia perforata at the inner termination of the fissure of Sylvius; the three roots of the olfactory nerve are seen upon the substantia perforata. The commencement of the transverse fissure on each side is concealed by the inner border of the middle lobe. 10. The commissure of the optic nerves; the numeral is placed between the optic nerves as they diverge from the commissure, and rests upon the lamina cinerea of the corpus callosum. 11. The tuber cinereum, from which the infundibulum is seen projecting. 12. The corpora albaeantia. 13. The locus perforatus, bounded on each side by the crura cerebri, and by the third nerve. 14. The pons Varolii. 15. The crus cerebelli of one side. 16. The fifth nerve emerging from the anterior border of the crus cerebelli; the small nerve by its side is the fourth. 17. The sixth pair
across the upper part of the medulla oblongata; and, contracting on each side into a thick rounded cord, enters the substance of the cerebellum under the name of crus cerebelli. There is a groove along its middle which lodges the basilar artery. The pons Varolii is the commissure of the cerebellum, and associates the two lateral lobes in their common function. Resting upon the pons, near its posterior border, is the sixth pair of nerves. On the anterior border of the crus cerebelli, at each side, is the thick bundle of filaments belonging to the fifth nerve, and, lying on its posterior border, the seventh pair of nerves. The upper surface of the pons forms a part of the floor of the fourth ventricle.

MEDULLA OBLONGATA.

The medulla oblongata (bulbus rhachidicus), is the upper enlarged portion of the spinal cord. It is somewhat conical in shape, and a little more than an inch in length, extending from the pons Varolii to a point corresponding with the upper border of the atlas. On the middle line, in front and behind, the medulla oblongata is marked by two vertical fissures, the fissura longitudinalis anterior and posterior, which divide it superficially into two symmetrical lateral cords or columns; whilst each lateral column is subdivided by minor grooves into three smaller cords, namely, the corpora pyramidalia, corpora olivaria, and corpora restiformia.

The Corpora pyramidalia are two narrow convex cords, tapering slightly from above downwards, and situated one on either side of the sulcus longitudinalis anterior. At about an inch below the pons the corpora pyramidalia communicate very freely across the sulcus by a decussation of their fibres, and at their point of entrance into the pons they are constricted into round cords. The fissura longitudinalis is somewhat enlarged by this constriction, and the enlarged space has received the name of foramen cœcum of the medulla oblongata.

The Corpora olivaria (named from some resemblance to the shape of an olive), are two oblong, oval-shaped, convex bodies, of about the same breadth with the corpora pyramidalia, about half an inch in length, and somewhat larger above than below. The corpus olivare is situated immediately external to the corpus pyramidale, from which, and from the corpus restiforme, it is separated by a well-marked groove. In this groove some longitudinal fibres are seen which enclose the base of the corpus olivare, and have been named funiculi siliquæ, those which lie to its inner side being the funiculus internus, and those to its outer side the funiculus externus. Besides these there are other fibres which cross the corpus olivare obliquely,

of nerves. 18. The seventh pair of nerves consisting of the auditory and facial. 19. The corpora pyramidalia of the medulla oblongata; the corpus olivare and part of the corpus restiforme are seen at each side. Just below the numeral is the decussation of the fibres of the corpora pyramidalia. 20. The eighth pair of nerves. 21. The ninth or hypoglossal nerve. 22. The anterior root of the first cervical spinal nerve.
these are the *fibræ arciformes*. When examined by section, the corpus olivare is found to be a ganglion deeply embedded in the medulla oblongata, and meeting its fellow at the middle line behind the corpus pyramidale. The ganglion of the corpus olivare (corpus dentatum, nucleus olivae), like that of the cerebellum, is a yellowish-grey dentated capsule, open behind, and containing medullary substance from which a fasciculus of fibres proceeds upwards to the corpora quadrigemina and thalami optici. The nervous filaments which spring from the groove on the inner side of the corpus olivare, are those of the hypoglossal nerve; and those on its outer side are the glossopharyngeal and pneumogastric.

The *Corpora restiformia* (restis, a rope), comprehend the whole of the posterior half of each lateral column of the medulla oblongata. They are separated from the corpora olivaria by the grooves already spoken of; posteriorly they are divided from each other by the fissura longitudinalis posterior and by the fourth ventricle, and superiorly they diverge and curve backwards to enter the cerebellum, and constitute its inferior peduncles. Along the posterior border of each corpus restiforme, and marked off from that body by a groove, is a narrow white cord, separated from its fellow by the fissura longitudinalis posterior. This pair of narrow cords are termed the *posterior median columns* or fasciculi (funiculi graciles). Each fasciculus forms an enlargement (processus clavatus) at its upper end, and is then lost in the corresponding corpus restiforme. The processus clavati are the lateral boundaries of the nib of the calamus scriptorius. The corpus restiforme is crossed near its entrance into the cerebellum, by the auditory nerve, the choroid plexus of the fourth ventricle, and the pneumogastric lobule.

The remaining portion of the medulla oblongata, visible from the exterior, are the two slightly convex columns which enter into the formation of the floor of the fourth ventricle. These columns are the funiculi teretes or posterior pyramids.

**DIVERGING FIBRES.**—The fibres composing the columns of the medulla oblongata have a special arrangement on reaching the upper part of that body, those of the corpora pyramidalia and olivaria enter the pons Varolii, and are thence prolonged through the crura cerebri, thalami optici, and corpora striata to the cerebral hemispheres; but those of the corpora restiformia are reflected backwards into the cerebellum and form its inferior peduncles.

From pursuing this course, and spreading out as they advance, these fibres have been termed by Gall the *diverging fibres*. While situated within the pons the fibres of the corpus pyramidale and olivare separate and spread out, and have grey substance interposed between them; and they quit the pons much increased in number and bulk, so as to form the *crus cerebri*. The fibres of the crus cerebri again are separated in the thalamus opticus, and are intermingled with grey matter, and they also quit that body greatly increased in number and bulk. Precisely the same change takes place in the
corpus striatum, and the fibres are now so extraordinarily multiplied as to be capable of forming a large proportion of the hemispheres.

Fig. 142.*

* The base of the brain, upon which several sections have been made, shewing the distribution of the diverging fibres. 1. The medulla oblongata. 2. One half of the pons Varolii. 3. The crus cerebi crossed by the optic nerve (4), and spreading out into the hemisphere to form the corona radiata. 5. The optic nerve near its origin; the nerves about the crus cerebri and cerebelli are the same as in the preceding figure. 6. The olfactory nerve. 7. The corpora albicantia. On the right side a portion of the brain has been removed to shew the distribution of the diverging fibres. 8. The fibres of the corpus pyramidale passing through the substance of the pons Varolii. 9. The fibres passing through the thalamus opticus. 10. The fibres passing through the corpus striatum. 11. Their distribution to the hemispheres. 12. The fifth nerve: its two roots may be traced, the one forwards to the fibres of the corpus pyramidale, the other backwards to the fasciculi teretes. 13. The fibres of the corpus pyramidale which pass outwards with the corpus restiforme into the substance of the cerebellum; these are the arciform fibres of Solly. The fibres referred to are those below the numeral, the numeral itself rests upon the corpus olivare. 14. A section through one of the hemispheres of the cerebellum, shewing the corpus rhomboideum in the centre of its white substance; the arbor vitae is also beautifully seen. 15. The opposite hemisphere of the cerebellum,
Observing this remarkable increase in the white fibres, apparently from the admixture of grey substance, Gall and Spurzheim considered the latter as the material of increase or formative substance to the white fibres, and they are borne out in this conclusion by several collateral facts, among the most prominent of which is the great vascularity of the grey substance; and the larger proportion of the nutrient fluid circulating through it, is fully capable of effecting the increased growth and nutrition of the structures by which it is surrounded. For a like reason the bodies in which this grey substance occurs, are called by the same physiologists "ganglia of increase," and by other authors simply ganglia. Thus the thalami optici and corpora striata are the ganglia of the cerebrum; or, in other words, the formative ganglia of the hemispheres.

The fibres of the corpora pyramidalia are not all of them destined to the course above described; several fasciculi curve outwards to reach the corpora restiformia, some passing in front and some behind the corpus olivare on each side. These are the arciform fibres, and they are distinguished by Mr. Solly into the superficial and deep cerebellar fibres. In the pons Varolii the continued or cerebral fibres (Solly) of the corpus pyramidalile are placed between the superficial and deep layers of transverse fibres, and escaping from the pons, constitute the inferior and inner segment of the crus cerebri. From the crus cerebri they pass for the most part beneath the thalami optici into the corpora striata.

The fibres which enclose the corpus olivare, under the name of fasciculi siliquae, are separated by that body into two bands; the innermost of the two bands, funiculus siliqua internus, accompanies the fibres of the corpus pyramidalile into the crus cerebri. The funiculus siliqua externus unites with a fasciculus proceeding from the nucleus oliva and the combined column ascending behind the crus cerebelli divides into a superior and an inferior band. The inferior band proceeds with a fasciculus presently to be described, the fasciculus innominatus into the upper segment of the crus cerebri. The superior band (laqueus) ascends by the side of the processus e cerebello ad testes, and crossing the latter obliquely enters the corpora quadrigemina, in which many of its fibres are distributed, while the rest are continued onwards into the thalamus opticus.

The corpora restiformia derive their fibres from the anterior as well as from the posterior columns of the medulla oblongata; they diverge as they approach the cerebellum, and leaving between them the cavity of the fourth ventricle enter the substance of the cerebellum, under the form of two rounded cords. These cords envelope the corpora rhomboidea, or ganglia of increase, and then expand on all sides so as to constitute the cerebellum.

Besides the fibres here described, there are in the interior of the medulla oblongata behind the corpora olivaria, and more or less apparent between these bodies and the corpora restiformia two large bundles of fibres, the fasciculi innominati. These fasciculi ascend behind
the deep transverse fibres of the pons Varolii and become apparent in the floor of the fourth ventricle, under the name of fasciculi teretes or posterior pyramids. From this point they are prolonged upwards beneath the corpora quadrigemina into the crura cerebri, of which they form the upper and outer segment, and are thence continued through the thalami optici and corpora striata into the hemispheres. The locus niger of the crus cerebri is a septum of grey matter interposed between these fasciculi and those of the corpora pyramidalia.

Converging Fibres.—In addition to the diverging fibres which are thus shown to constitute both the cerebrum and cerebellum, by their increase and development, another set of fibres are found to exist, which have for their office the association of the symmetrical halves, and distant parts of the same hemispheres.

These are called from their direction converging fibres, and from their office commissures. The commissures of the cerebrum and cerebellum are the—

Corpus callosum,
Fornix,
Septum lucidum,
Anterior commissure,
Middle commissure,
Posterior commissure,
Peduncles of the pineal gland,
Pons Varolii.

The Corpus callosum is the commissure of the hemispheres. It is therefore of moderate thickness in the middle, where its fibres pass directly from one hemisphere to the other; thicker in front, where the anterior lobes are connected; and thickest behind, where the fibres from the posterior lobes are assembled. The fibres which curve backwards into the posterior lobes from the posterior border of the corpus callosum have been termed forceps, those which pass directly outwards into the middle lobes from the same point, tapetum, and those which curve forwards and inwards from the anterior border to the anterior lobes, forceps anterior.

The Fornix is an antero-posterior commissure, and serves to connect a number of parts. Below it is associated with the thalami optici; on each side, by means of the corpora fimbriata, with the middle lobes of the brain; and, above, with the corpus callosum, and consequently with the hemispheres.

The Septum lucidum is a perpendicular commissure between the fornix and corpus callosum.

The Anterior commissure traverses the corpus striatum, and connects the anterior and middle lobes of opposite hemispheres.

The Middle commissure is a layer of grey substance, uniting the thalami optici.

The Posterior commissure is a white rounded cord, connecting the thalami optici.
The Peduncles of the pineal gland must also be regarded as commissures, assisted in their function by the grey substance of the gland.

The Pons Varolii is the commissure to the two hemispheres of the cerebellum. It consists of transverse fibres, which are split into two layers by the passage of the fasciculi of the corpora pyramidalia and olivaria. These two layers, the superior and inferior, are collected together on each side, in the formation of the crura cerebelli.

**SPINAL CORD.**

The dissection of the spinal cord requires that the spinal column should be opened throughout its entire length by sawing through the laminae of the vertebrae, close to the roots of the transverse processes, and raising the arches with a chisel; the muscles of the back having been removed as a preliminary step.

The Spinal column contains the spinal cord, or medulla spinalis; the roots of the spinal nerves; and the membranes of the cord, viz. the dura mater, arachnoid, pia mater, and membrana dentata.

The Dura mater spinalis (theca vertebralis) is a cylindrical sheath of fibrous membrane, identical in structure with the dura mater of the skull, and continuous with that membrane. At the margin of the occipital foramen it is closely adherent to the bone; by its anterior surface it is attached to the posterior common ligament, and below by means of its pointed extremity to the coccyx. In the rest of its extent it is comparatively free, being connected, by a very loose areolar tissue only, to the walls of the spinal canal. In this areolar tissue there exists a quantity of reddish, oily, adipose substance, somewhat analogous to the marrow of long bones. On either side and below, the dura mater forms a sheath for each of the spinal nerves, to which it is closely adherent. Upon its inner surface it is smooth, being lined by the arachnoid; and on its sides may be seen double openings for the two roots of each of the spinal nerves.

The Arachnoid is a continuation of the serous membrane of the brain. It encloses the cord very loosely, being connected to it only by long slender filaments of fibro-cellular tissue, and by a longitudinal lamella which is attached to the posterior aspect of the cord. The fibro-cellular tissue is most abundant in the cervical region, and diminishes in quantity from above downwards; and the longitudinal lamella is complete only in the dorsal region. The arachnoid passes off on either side with the spinal nerves, to which it forms a sheath; and is then reflected upon the dura mater, to constitute its serous surface. A connection exists in several situations between the arachnoid of the cord and that of the dura mater. The space between the arachnoid and the spinal cord is identical with that already described as existing between the same parts in the brain, the sub-arachnoidean space. It is occupied by a serous fluid, sufficient in quantity to expand the arachnoid, and fill completely the cavity of the theca.
vertebralis. The sub-arachnoidean fluid keeps up a constant and gentle pressure upon the entire surface of the brain and spinal cord, and yields with the greatest facility to the various movements of the cord, giving to those delicate structures the advantage of the principles so usefully applied by Dr. Arnott in the hydrostatic bed.

The Pia mater is the immediate investment of the cord; and, like the other membranes, is continuous with that of the brain. It is not, however, like the pia mater cerebri, a vascular membrane; but is dense and fibrous in its structure, and contains few vessels. It invests the cord closely, and sends a duplication into the fissura longitudinalis anterior, and another, extremely delicate, into the fissura longitudinalis posterior. It forms a sheath for each of the filaments of the nerves, and for the nerves themselves; and, inferiorly, at the conical termination of the cord, is prolonged downwards as a slender ligament (filum terminale), which descends through the centre of the cauda equina, and is attached to the dura mater lining the canal of the coccyx. This attachment is a rudiment of the original extension of the spinal cord into the canal of the sacrum and coccyx.

The Membrana dentata (ligamentum dentatum) is a thin process of pia mater sent off from each side of the cord throughout its entire length, and separating the anterior from the posterior roots of the spinal nerves. The number of serrations on each side is about twenty, the first being situated on a level with the occipital foramen, and having the vertebral artery and hypoglossal nerve passing in front and the spinal accessory nerve behind it, and the last opposite the first or second lumbar vertebra. Below this point the membrana dentata is lost in the filum terminale of the pia mater. The use of this membrane is to maintain the position of the spinal cord in the midst of the fluid by which it is surrounded.

The Spinal cord of the adult extends from the pons Varolii to opposite the first or second lumbar vertebra, where it terminates in a rounded point; in the child, at birth, it reaches to the middle of the third lumbar vertebra, and in the embryo is prolonged as far as the coccyx. It presents a difference of diameter in different parts of its extent, and exhibits three enlargements. The uppermost of these is the medulla oblongata; the next corresponds with the origin of the nerves destined to the upper extremities; and the lower enlargement is situated near its termination, and corresponds with the attachment of the nerves which are intended for the supply of the lower limb.

In form, the spinal cord is a flattened cylinder, and presents on its anterior surface a fissure, which extends into the cord to the depth of one third of its diameter. This is the fissura longitudinalis anterior. If the sides of the fissure be gently separated, they will be seen to be connected at the bottom by a layer of medullary substance, the anterior commissure.

On the posterior surface another fissure exists, which is so narrow as to be hardly perceptible without careful examination. This is the
fissura longitudinalis posterior. It extends more deeply into the cord than the anterior fissure, and terminates in the grey substance of the interior. These two fissures divide the medulla spinalis into two lateral cords, which are connected to each other by the white commissure which forms the bottom of the anterior longitudinal fissure, and by a commissure of grey matter situated behind the former. On either side of the fissura longitudinalis posterior is a slight line, which bounds on each side the posterior median columns. These columns are most apparent at the upper part of the cord, near the fourth ventricle, where they are separated by the point of the calamus scriptorius, and where they form a bulbous enlargement at each side, called the processus clavatus.

Two other lines are observed on the medulla, the anterior and posterior lateral sulci, corresponding with the attachment of the anterior and posterior roots of the spinal nerves. The anterior lateral sulcus is a mere trace, marked only by the attachment of the filaments of the anterior roots. The posterior lateral sulcus is more evident, and is a narrow greyish line derived from the grey substance of the interior.

Although these fissures and sulci indicate a division of the spinal cord into three pairs of columns, namely, anterior, lateral, and posterior, the posterior median columns being regarded as a part of the posterior columns, it is customary to consider each half of the spinal cord as consisting of two columns only, the antero-lateral and the posterior. The antero-lateral columns are the columns of motion, and comprehend all that part of the cord situated between the fissura longitudinalis anterior and the posterior lateral sulcus, the grey line of origin of the posterior roots of the spinal nerves. The posterior columns are the columns of sensation.

If a transverse section of the spinal cord be made, its internal structure may be seen and examined. It would then appear to be composed of two hollow cylinders of white matter, placed side by side, and connected by a narrow white commissure. Each cylinder is filled with grey substance, which is connected by a commissure of the same matter. The form of the grey substance, as observed in the section, is that of two half-moons placed back to back, and joined by a transverse band. The horns of the moons correspond to the sulci of origin of the anterior and posterior roots of the nerves. The anterior horns, larger than the posterior, do not quite reach this surface; but the posterior appear upon the surface, and form a narrow grey line, the sulcus lateralis posterior.

The white substance of the spinal cord is composed of parallel fibres which are collected into longitudinal laminae and extend throughout the entire length of the cord. These laminae are various in breadth, and are arranged in a radiated manner; one border being thick and corresponding with the surface of the cord, while the other is thin and lies in contact with the grey substance of the interior. According to Rolando the white substance constitutes a simple nervous membrane, which is folded into longitudinal plaits, having the radiated disposition.
above described. The anterior commissure, according to his description, is merely the continuation of this nervous membrane from one lateral cord across the middle line to the other. Moreover, Rolando considers that a thin lamina of pia mater is received between each of the folds from the exterior, while a layer of the grey substance is prolonged between them from within. Cruveilhier is of opinion that each lamella is completely independent of its neighbours, and he believes this statement to be confirmed by pathology, which shows that a single lamella may be injured or atrophied, and at the same time be surrounded by others perfectly sound.

CRANIAL NERVES.

There are *nine pairs* of cranial nerves. Taken in their order from before, backwards, they are as follows:

1st. Olfactory.
2nd. Optic.
3rd. Motores oculorum.
4th. Pathetici (trochlears).
5th. Trifacial (trigemini).
6th. Abducentes.
7th. Facial (portio dura),
     Auditory (portio mollis),
     Glosso-pharyngeal,
8th. Pneumogastric (vagus, par vagum),
     Spinal accessory.
9th. Hypoglossal (lingual).

Functionally or physiologically the cranial nerves admit of division into three groups, namely, nerves of special sense, nerves of motion, and compound nerves, that is, nerves which contain fibres both of sensation and motion. The nerves belonging to these groups are the following:

<table>
<thead>
<tr>
<th>Special sense</th>
<th>Motion</th>
<th>Compound</th>
</tr>
</thead>
<tbody>
<tr>
<td>5th. Trifacial.</td>
<td>7th. Facial.</td>
<td></td>
</tr>
<tr>
<td>9th. Hypoglossal.</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
The fourth, facial and eighth nerves were considered by Sir Charles Bell to form a system apart from the rest, and to be allied in the functions of expression and respiration. In consonance with this view he termed them *respiratory nerves*, and he gave to that part of the medulla oblongata from which they arise the name of *respiratory tract*.

**First pair. Olfactory.**—The olfactory nerve arises by three roots; an *inner root* from the substantia perforata, a *middle root* from

*The olfactory nerve, with its distribution on the septum nasi. The nares have been divided by a longitudinal section made immediately to the left of the septum, the right nares being preserved entire. 1. The frontal sinus. 2. The nasal bone. 3. The crista galli process of the ethmoid bone. 4. The sphenoidal sinus of the left side. 5. The sella turcica. 6. The basilar process of the sphenoid and occipital bones. 7. The posterior opening of the right nares. 8. The opening of the Eustachian tube in the upper part of the pharynx. 9. The soft palate, divided through its middle. 10. Cut surface of the hard palate. a. The olfactory nerve. b. Its three roots of origin. c. Its bulb, from which the filaments are seen proceeding which spread out in the substance of the pituitary membrane. d. The nasal nerve, a branch of the ophthalmic nerve descending into the left nares from the anterior foramen of the cribiform plate, and dividing into its external and internal branch. e. The naso-palatine nerve, a branch of the sphenopalatine ganglion distributing twigs to the mucous membrane of the septum nasi in its course to (f) the anterior palatine foramen, where it forms a small gangliform swelling (Cloquet's ganglion) by its union with its fellow of the opposite side. g. Branches of the naso-palatine nerve to the palate. h. Posterior palatine nerves. i, i. The septum nasi.*
a papilla of grey matter (caruncula mamillaris), embedded in the anterior lobe, and an external root, which may be traced as a white streak along the fissure of Sylvius into the corpus striatum, where it is continuous with some of the fibres of the anterior commissure. The nervous cord formed by the union of these three roots is soft in texture, prismatic in shape, and embedded in a sulcus between two convolutions on the under surface of each anterior lobe of the brain, lying between the pia mater and the arachnoid. As it passes forwards it increases in breadth and swells at its extremity into an oblong mass of grey and white substance, the bulbus olfactorius, which rests upon the cribiform lamella of the ethmoid bone. From the under surface of the bulbus olfactorius are given off the nerves which pass through the cribiform foramina and supply the mucous membrane of the nares; they are arranged into two groups, an inner group, reddish in colour and soft, which spread out upon the septum narium, and an outer group, whiter and more firm, which descend through bony canals in the outer wall of the nares, and are distributed upon the superior and middle turbinated bones.

Second pair. Optic.—The optic nerve, a nerve of large size, arises from the corpora geniculata on the posterior and inferior aspect

Fig. 144.*

* The isthmus encephali, shewing the thalamus opticus, corpora quadrigemina, pons Varolii, and medulla oblongata as viewed from the side. 1. The thalamus opticus. 2. The posterior prominence of this body, tuberculum superius posterior or pulvinar. 3. The corpus geniculatum externum. 4. The corpus geniculatum internum. 5. The commencement of the tractus opticus. 6. The pineal gland. 7. The nates. 8. The testis of one side. 9. The bra-
of the thalamus opticus and from the nates. Proceeding from this origin it winds around the crus cerebri as a flattened band, under the name of tractus opticus, and joins with its fellow in front of the tuber cinereum to form the optic commissure (chiasma). The tractus opticus is united with the crus cerebri and tuber cinereum, and is covered in by the pia mater; the commissure is also connected with the tuber cinereum, from which it receives fibres, and the nerve beyond the commissure diverges from its fellow, becomes rounded in form, and is enclosed in a sheath derived from the arachnoid. In passing through the optic foramen the optic nerve receives a sheath from the dura mater, which splits at this point into two layers; one, which becomes the periosteum of the orbit; the other, the one in question, which forms the sheath for the nerve, and is lost in the sclerotic coat of the eyeball. After a short course within the orbit the optic nerve pierces the sclerotic and choroid coats and expands into the nervous membrane of the eyeball, the retina. Near the globe, the nerve is pierced by a small artery, the arteria centralis retinae, which runs through the central axis of the nerve and reaches the internal surface of the retina, to which it distributes branches.

The commissure rests upon the processus olivaris of the sphenoid bone; it is bounded by the lamina cinerea of the corpus callosum in front, by the substantia perforata on each side, and by the tuber cinereum behind. Within the commissure the innermost fibres of the optic nerves cross each other to pass to opposite eyes, while the outer fibres continue their course uninterruptedly to the eye of the corresponding side. The neurilemma of the commissure, as well as that of the nerves, is formed by the pia mater.

Third pair. Motores Oculorum.—The motor oculi, a nerve of moderate size, arises from the inner side of the crus cerebri, close to the pons Varolii, and passes forward between the posterior cerebral and superior cerebellar artery. It pierces the dura mater immediately in front of the posterior clinoid process; descends obliquely

chium anterius of the corpora quadrigemina. a. Their brachium posterior. b. The origin of the fourth nerve, which may be seen descending over the crus cerebri. c. The processus e cerebello ad testem, or superior peduncle of the cerebellum. d. The band of fibres termed laqueus, the superior division of the fasciculus olivaris crossing the superior peduncle of the cerebellum to enter the corpora quadrigemina. Through the small triangular space in front of this band, crossed by the fourth nerve, some of the fibres of the superior peduncle of the cerebellum may be seen. e. The superior portion of the crus cerebri, termed tegmentum. f. Its inferior portion. g. The third nerve. h. The pons Varolii. i. The crus cerebelli, or middle peduncle of the cerebellum. k. The inferior peduncle derived from the corpus restiforme. The mass lying in the angular interval upon these is the superior peduncle. l. The fifth nerve issuing from between the transverse fasciculi of the pons Varolii. m. The sixth nerve. n. The seventh nerve; the inferior and smaller cord is the facial nerve, the superior and larger the auditory. o. The corpus olivare crossed inferiorly by the superficial arciform fibres. p. The corpus pyramidale. q. The median posterior fasciculi of the medulla oblongata. r. The corpus restiforme. s. The spinal cord. t. The fourth ventricle.
along the external wall of the cavernous sinus; and divides into two branches which enter the orbit between the two heads of the external rectus muscle. The superior branch ascends, and supplies the superior rectus and levator palpebrae. The inferior sends a branch beneath the optic nerve to the internal rectus, another to the inferior rectus, and a long branch to the inferior oblique muscle. From the latter a short thick branch is given off to the ciliary ganglion, forming its inferior root.

The fibres of origin of this nerve may be traced into the grey substance of the crus cerebri,* into the motor tract,† and as far as the superior fibres of the crus cerebri.‡ In the cavernous sinus it receives one or two filaments from the cavernous plexus, and one from the ophthalmic nerve.

**Fourth pair. Pathetic (trochlearis).**—The fourth is the smallest cerebral nerve; it arises from the valve of Vieussens close to the testis, and winding around the crus cerebri to the extremity of the petrous portion of the temporal bone, pierces the dura mater near the oval opening for the fifth nerve, and passes along the outer wall of the cavernous sinus to the sphenoidal fissure. In its course through the sinus it is situated at first below the motor oculi, but afterwards ascends and becomes the highest of the nerves which enter the orbit through the sphenoidal fissure. Upon entering the orbit the nerve crosses the levator palpebrae muscle near its origin, and is distributed upon the orbital surface of the superior oblique or trochlearis muscle; hence its synonym trochlearis.

**Branches.**—While in the cavernous sinus the fourth nerve gives off a recurrent branch, some filaments of communication to the ophthalmic nerve, and a branch to assist in forming the lachrymal nerve; the recurrent branch, which consists of sympathetic filaments derived from the carotid plexus, passes backwards between the layers of the tentorium, and divides into two or three filaments, which are distributed to the lining membrane of the lateral sinus. This nerve is sometimes a branch of the ophthalmic, and occasionally proceeds directly from the carotid plexus.

**Fifth pair. Trifacial (trigeminus).**—The fifth nerve, the great sensitive nerve of the head and face, and the largest cranial nerve, is analogous to the spinal nerves in its origin by two roots, from the anterior and posterior columns of the spinal cord, and in the existence of a ganglion on the posterior root. It arises§ from a tract of yellowish white matter situated in front of the floor of the fourth ventricle and the origin of the auditory nerve, and behind the crus cerebelli. This tract divides inferiorly into two fasciculi which may be traced downwards into the spinal cord, one being continuous with

* Mayo. † Solly. ‡ Grainger.
§ I have adopted the origin of this nerve, given by Dr. Alcock, of Dublin, as the result of his dissections, in the Cyclopaedia of Anatomy and Physiology. Mr. Mayo also traces the anterior root of the nerve to a similar origin.
the fibres of the anterior column, the other with the posterior column. Proceeding from this origin the two roots of the nerve pass forward, and issue from the brain upon the anterior part of the crus cerebelli, where they are separated by a slight interval. The anterior is much smaller than the posterior, and the two together constitute the fifth nerve, which in this situation consists of seventy to a hundred filaments held together by pia mater. The nerve then passes through an oval opening in the border of the tentorium, near the extremity of the petrous bone, and spreads out into a large semilunar ganglion, the Casserian. If the ganglion be turned over, it will be seen that the anterior root lies against its under surface without having any connection with it, and may be followed onwards to the inferior maxillary nerve. The Casserian ganglion divides into three branches, the ophthalmic, superior maxillary, and inferior maxillary.

The Ophthalmic Nerve is a short trunk, being not more than three quarters of an inch in length; it arises from the upper angle of the Casserian ganglion, beneath the dura mater, and passes forwards through the outer wall of the cavernous sinus, lying externally to the other nerves; it divides into three branches. Previously to its division it receives several filaments from the carotid plexus, and gives off a small recurrent nerve, that passes backwards with the recurrent branch of the fourth nerve between the two layers of the tentorium to the lining membrane of the lateral sinus.

The Branches of the ophthalmic nerve are, the—

Frontal,
Lachrymal,
Nasal.

The Frontal nerve mounts above the levator palpebræ, and runs forward, resting upon that muscle, to the supra-orbital foramen, through which it escapes upon the forehead, with the supra-orbital artery. It supplies the conjunctiva and upper eyelid and the integument of the cranium as far as the vertex.

The frontal nerve gives off but one small branch, the supra-trochlear, which passes inwards above the pulley of the superior oblique muscle, and ascends along the middle line of the forehead, distributing filaments to the integument, to the inner angle of the eye and root of the nose, and to the conjunctiva.

The Lachrymal nerve, the smallest of the three branches of the ophthalmic, receives a filament from the fourth nerve in the cavernous sinus, and passes outwards along the upper border of the external rectus muscle, and in company with the lachrymal artery, to the lachrymal gland, where it divides into two branches. The superior branch passes along the upper surface of the gland and through a foramen in the malar bone, and is distributed upon the temple and cheek, communicating with the subcutaneous male and facial nerves.
The inferior branch supplies the lower surface of the gland and conjunctiva, and terminates in the integument of the upper lid communicating with the facial nerve.

The *Nasal* nerve (naso-ciliaris) passes forwards between the two
heads of the external rectus muscle, crosses the optic nerve in company with the ophthalmic artery, and enters the anterior ethmoidal foramen immediately above the internal rectus. It then traverses the upper part of the ethmoid bone to the cribiform plate, and passes downwards through the slit-like opening by the side of the crista galli into the nose, where it divides into two branches— an internal branch supplying the mucous membrane, near the anterior openings of the nares; and an external branch which passes between the fibro-cartilages, and is distributed to the integument at the extremity of the nose.

The Branches of the nasal nerve within the orbit are, the ganglionic, ciliary, and infra-trochlear; in the nose it gives off one or two filaments to the anterior ethmoidal cells and frontal sinus. The ganglionic branch passes obliquely forwards to the superior angle of the ciliary ganglion, forming its superior or long root. The ciliary branches are two or three filaments which are given off by the nasal as it crosses the optic nerve. They pierce the posterior part of the sclerotic, and pass between that tunic and the choroid to be distributed to the iris. The infra-trochlear is given off just as the nerve is about to enter the anterior ethmoidal foramen. It passes along the superior border of the internal rectus to the inner angle of the eye, where it communicates with the supra-trochlear nerve, and supplies the lachrymal sac, caruncula lachrymalis, conjunctiva, and inner angle of the orbit.

The Superior maxillary nerve, larger than the preceding, proceeds from the middle of the Casserian ganglion; it passes forwards through the foramen rotundum, crosses the spheno-maxillary fossa, and enters the canal in the floor of the orbit, along which it runs to the infra-orbital foramen. Emerging on the face, beneath the levator labii superioris muscle, it divides into a number of branches, which are distributed to the lower eyelid and conjunctiva, and to the muscles and integument of the upper lip, nose, and cheek, forming a plexus with the facial nerve.

The Branches of the superior maxillary nerve are divisible into three groups:—1. Those which are given off in the spheno-maxillary fossa. 2. Those in the infra-orbital canal; and 3. Those on the face. They may be thus arranged:

\[
\begin{align*}
\text{Spheno-maxillary fossa,} & \quad \begin{cases}
\text{Orbital,} \\
\text{Two from Meckel's ganglion,} \\
\text{Posterior dental.}
\end{cases} \\
\text{Infra-orbital canal,} & \quad \begin{cases}
\text{Middle dental,} \\
\text{Anterior dental.}
\end{cases} \\
\text{On the face,} & \quad \begin{cases}
\text{Muscular,} \\
\text{Cutaneous.}
\end{cases}
\end{align*}
\]

The Orbital branch (n. subcutaneus maxae) enters the orbit through
the sphenomaxillary fissure, and divides into two branches, temporal and malar; the temporal branch ascends along the outer wall of the orbit, and, after receiving a branch from the lachrymal nerve, passes through a canal in the malar bone and enters the temporal fossa; it then pierces the temporal muscle and fascia and is distributed to the integument of the temple and side of the forehead, communicating with the facial and anterior auricular nerve. In the temporal fossa it communicates with the deep temporal nerves. The malar, or inferior branch, takes its course along the lower angle of the outer wall of the orbit, and emerges upon the cheek through an opening in the malar bone, passing between the fibres of the orbicularis palpebrarum muscle. It communicates with branches of the infra-orbital and facial nerves.

The two branches from Meckel's ganglion ascend from that body to join the nerve, as it crosses the sphenomaxillary fossa.

The posterior dental branches pass through small foramina in the posterior surface of the superior maxillary bone, and running forwards in the base of the alveolus, supply the posterior teeth and gums.

The middle and anterior dental branches descend to the corresponding teeth and gums; the former beneath the lining membrane of the antrum, the latter through distinct canals in the walls of the bone. Previously to their distribution, the dental nerves form a plexus (superior maxillary plexus) in the outer wall of the superior maxillary bone immediately above the alveolus. From this plexus the filaments are given off which supply the pulps of the teeth, the gums, the mucous membrane of the floor of the nares, and the palate. Some gangliform masses have been described in connection with this plexus, one being placed over the canine, and another over the second molar tooth.

The muscular and cutaneous branches are the terminating filaments of the nerve; they supply the muscles, integument, and mucous membrane of the cheek, nose, and lip, and form an intricate plexus with branches of the facial nerve.

The inferior maxillary nerve proceeds from the inferior angle of the Casserian ganglion; it is the largest of the three divisions of the fifth nerve, and is augmented in size by the anterior or motor root, which passes behind the ganglion, and unites with the inferior maxillary as it escapes through the foramen ovale. Emerging at the foramen ovale the nerve divides into two trunks, external and internal, which are separated from each other by the external pterygoid muscle.

The external trunk, into which may be traced nearly the whole of the motor root, immediately divides into five branches which are distributed to the muscles of the temporo-maxillary region; they are—

The masseteric, which crosses the sigmoid notch with the masseteric artery to the masseter muscle. It sends a small branch to the temporal muscle, and a filament to the temporo-maxillary articulation.

Temporal; two branches passing between the upper border of the external pterygoid muscle and the temporal bone to the temporal
muscle. Two or three filaments from these nerves pierce the temporal fascia, and communicate with the lachrymal, sub-cutaneous malæ, auricular and facial nerve.

 Buccal; a large branch which pierces the fibres of the external pterygoid, to reach the buccinator muscle. This nerve sends filaments to the temporal and external pterygoid muscle, to the mucous membrane and integument of the cheek, and communicates with the facial nerve.

 Internal pterygoid; a long and slender branch, which passes inwards to the internal pterygoid muscle, and gives filaments in its course to the tensor palati and tensor tympani. This nerve is remarkable from its connection with the otic ganglion, to which it is closely attached.

The Internal trunk divides into three branches—

Gustatory,
Inferior dental,
Anterior auricular.

The Gustatory nerve descends between the two pterygoid muscles to the side of the tongue, where it becomes flattened, and divides into numerous filaments, which are distributed to the papillae and mucous membrane.

Relations.—It lies at first between the external pterygoid muscle and the pharynx, next between the two pterygoid muscles, then between the internal pterygoid and ramus of the jaw, and between the stylo-glossus muscle and the submaxillary gland; lastly, it runs along the side of the tongue, resting upon the hyo-glossus muscle, and covered in by the mylo-hyoides and mucous membrane.

The gustatory nerve, while between the two pterygoid muscles, receives a branch from the inferior dental; lower down it is joined at an acute angle by the chorda tympani which passes downwards in the sheath of the gustatory to the submaxillary gland, where it unites with the submaxillary ganglion. On the hyo-glossus muscle some branches of communication are sent to the hypoglossal, and in the course of the nerve several small branches to the mucous membrane of the fauces, to the tonsils, submaxillary gland, Wharton’s duct, and sublingual gland.

The Inferior dental nerve passes downwards with the inferior dental artery, at first between the two pterygoid muscles, and then between the internal lateral ligament and the ramus of the lower jaw, to the dental foramen. It then runs along the canal in the inferior maxillary bone, distributing branches (inferior maxillary plexus) to the teeth and gums, and divides into two terminal branches, incisive and mental. The incisive branch passes forwards, to supply the incisive teeth; the mental branch escapes through the mental foramen, to be distributed to the muscles and integument of the chin and lower lip, and to the mucous membrane of the latter, communicating with the facial nerve.
The inferior dental nerve gives off but one branch, the mylo-hyoidean, which leaves the nerve just as it is about to enter the dental foramen. This branch pierces the insertion of the internal lateral ligament, and descends along a groove in the bone to the inferior surface of the mylo-hyoid muscle, to which, and to the anterior belly of the digastricus, it is distributed.

The Anterior auricular nerve originates by two roots, between which the arteria meningea media takes its course, and passes directly backwards behind the articulation of the lower jaw, against which it rests. In this situation it divides into two branches, which reunite, and form a kind of plexus. From the plexus two branches are given off—ascending and descending. The ascending or temporal branch sends one or two considerable branches of communication to the facial nerve, and then ascends in front of the ear to the temporal region, upon which it is distributed in company with the branches of the temporal artery. In its course it sends filaments to the temporo-maxillary articulation, to the pinna and meatus of the ear, and to the integument in the temporal region. It communicates on the temple with branches of the facial, supra-orbital, lachrymal, and subcutaneous malar nerve. The descending branch enters the parotid gland, to which it sends numerous branches; it communicates with the inferior dental and auricularis magnus nerve, and supplies the external ear, the meatus auditorius, and the temporo-maxillary articulation, and sends one or two filaments into the tympanum.

Sixth pair. Abducentes.—The abducens nerve, about half the size of the motor oculi, arises by several filaments from the upper constricted part of the corpus pyramidale close to the pons Varolii. Proceeding forwards from this origin it lies parallel with the basilar artery, and, piercing the dura mater upon the clivus Blumenbachii of the sphenoid bone, ascends beneath that membrane to the cavernous sinus. It then runs forwards along the inner wall of the sinus below the other nerves, and, resting against the internal carotid artery, passes between the two heads of the external rectus, and is distributed to that muscle. As it enters the orbit, it lies upon the ophthalmic vein, from which it is separated by a lamina of dura mater. In the cavernous sinus it is joined by several filaments from the carotid plexus, by one from Meckel's ganglion, and one from the ophthalmic nerve. Mr. Mayo traced the origin of this nerve between the fasciculi of the corpora pyramidalia to the posterior part of the medulla oblongata; and Mr. Grainger pointed out its connection with the grey substance of the spinal cord.

Seventh pair.—The seventh pair consists of two nerves which lie side by side on the posterior border of the crus cereblli. The smaller and most internal of these, and, at the same time, the most dense in texture, is the facial nerve or portio dura. The external nerve, which is soft and pulpy, and often grooved by contact with the preceding, is
the auditory nerve or portio mollis of the seventh pair. Soemmering
makes the auditory nerve the eighth pair; but, retaining the classifi-
cation of Willis, we regard it as a part of the seventh with the
facial.

**Facial nerve.** (Portio dura).—The facial nerve arises from the
upper part of the groove between the corpus olivare and corpus resti-
forme, close to the pons Varolii, from which point its fibres may be
traced deeply into the corpus restiforme. The nerve then passes for-
wards, resting upon the crus cerebelli, and comes into relation with the
auditory nerve, with which it enters the meatus auditorius internus,
lying at first to the inner side of, and then upon that nerve. At the
bottom of the meatus it enters the canal expressly intended for it, the
aqueductus Fallopii, and directs its course forwards towards the hiatus
Fallopii, where it forms a gangliform swelling (intumescentia gangli-
formis), and receives the petrosal branch of the Vidian nerve. It then
curves backwards towards the tympanum, and descends along the inner
wall of that cavity to the stylo-mastoid foramen. Emerging at the
stylo-mastoid foramen it passes forwards within the parotid gland,
crossing the external jugular vein and external carotid artery, and at
the ramus of the lower jaw divides into two trunks, temporo-facial and
cervico-facial. These trunks at once split into numerous branches
which, after forming a number of looped communications (pes anseri-
nus) with each other over the masseter muscle, spread out upon the
side of the face, from the temple to the neck, to be distributed to the
muscles of this extensive region. The communications which the facial
nerve maintains in its course are the following: in the meatus audito-
rius, it sends one or two filaments to the auditory nerve; the intu-
mescentia gangliformis receives the nervus petrosus superficialis major
and minor, and sends a twig back to the auditory nerve; behind the
tympanum the nerve receives one or two twigs from the auricular
branch of the pneumogastric; at its exit from the stylo-mastoid forae-
men it receives a twig from the glosso-pharyngeal, and in the parotid
gland one or two large branches from the anterior auricular nerve.
Besides these, the facial nerve has numerous peripheral communica-
tions, with the branches of the fifth nerve on the face, and of the cer-
vical nerves in the parotid gland and neck. The numerous communi-
cations of the facial nerve obtained for it the designation of nervus
sympatheticus minor.

The Branches of the facial nerve are—

- **Within the aqueductus Fallopii.**
  - Tympanic,
  - Chorda tympani.
- **After emerging at the stylo-mastoid foramen,**
  - Posterior auricular,
  - Stylo-hyoid,
  - Digastric.
- **On the face,**
  - Temporo-facial,
  - Cervico-facial.
The **Tympanic** branch is a small filament distributed to the stapedius muscle.

The **Chorda tympani** quits the facial just before that nerve emerges from the stylo-mastoid foramen, and ascends by a distinct canal to the upper part of the posterior wall of the tympanum, where it enters

---

* The distribution of the facial nerve and the branches of the cervical plexus.
  1. The facial nerve, escaping from the stylo-mastoid foramen, and crossing the ramus of the lower jaw; the parotid gland has been removed in order to see the nerve more distinctly. 2. The posterior auricular branch; the digastric and stylo-mastoid filaments are seen near the origin of this branch. 3. Temporal branches, communicating with (4) the branches of the frontal nerve. 5. Facial branches, communicating with (6) the infra-orbital nerve. 7. Facial branches, communicating with (8) the mental nerve. 9. Cervico-facial branches, communicating with (10) the superficialis colli nerve, and forming a plexus (11) over the submaxillary gland. The distribution of the branches of the facial in a radiated direction over the side of the face and their looped communications constitute the pes anserinus. 12. The auricularis magnus nerve, one of the ascending branches of the cervical plexus. 13. The occipitalis minor, ascending along the posterior border of the sterno-mastoid muscle. 14. The superficial and deep descending branches of the cervical plexus. 15. The spinal accessory nerve, giving off a branch to the external surface of the trapezius muscle. 16. The occipitalis major nerve, the posterior branch of the second cervical nerve.
that cavity through an opening situated between the base of the pyramid and the attachment of the membrana tympani, and becomes invested by mucous membrane. It then crosses the tympanum between the handle of the malleus and long process of the incus to the anterior inferior angle of the cavity, and escapes through a distinct opening in the fissura Glaseri, and joins the gustatory nerve at an acute angle between the two pterygoid muscles. Enclosed in the sheath of the gustatory nerve, it descends to the submaxillary gland, where it unites with the submaxillary ganglion.

The *Posterior auricular* nerve ascends behind the ear, between the meatus and mastoid process, and divides into an anterior and a posterior branch. The *anterior* branch receives a filament of communication from the auricular branch of the pneumogastric nerve, and distributes filaments to the retrahens and atollens aurem muscles and to the pinna. The *posterior* branch communicates with the auricularis magnus and occipitalis minor; and is distributed to the posterior belly of the occipito-frontalis. The *Stylo-hyoid* branch is distributed to the stylo-hyoid muscle.

The *Digastric* branch supplies the posterior belly of the digastricus muscle, and communicates with the glosso-pharyngeal and pneumogastric nerve. The *Temporo-facial* gives off a number of branches which are distributed over the temple and upper half of the face, supplying the muscles of this region, and communicating with the branches of the auricular, the subcutaneous male, and the supra-orbital nerve. The inferior branches, which accompany Stenon's duct, and form a plexus with the terminal branches of the infra-orbital nerve.

The *Cervico-facial* divides into a number of branches that are distributed to muscles on the lower half of the face and upper part of the neck. The cervical branches form a plexus with the superficialis colli nerve over the submaxillary gland, and are distributed to the platysma myoides.

**AUDITORY NERVE** (portio mollis).—The auditory nerve takes its origin in the lineæ transverse (striae medullares) of the anterior wall or floor of the fourth ventricle, and winds around the corpus restiforme, from which it receives fibres, to the posterior border of the crus cerebelli. It then passes forwards upon the crus cerebelli in company with the facial nerve, which lies in a groove on its superior surface, and enters the meatus auditorius internus, and at the bottom of the meatus it divides into two branches, *cochlear* and *vestibular*. The auditory nerve is soft and pulpy in texture, and receives in the meatus auditorius several filaments from the facial nerve.

**EIGHTH PAIR.**—The eighth pair consists of three nerves, glosso-pharyngeal, pneumogastric, and spinal accessory; these are the ninth, tenth, and eleventh pairs of Soemmering.

**GLOSso-PHARYNGEAL NERVE.**—The glosso-pharyngeal nerve arises...
by five or six filaments from the groove between the corpus olivare and restiforme, and escapes from the skull at the innermost extremity of the jugular foramen through a distinct opening in the dura mater, lying anteriorly to the sheath of the pneumogastric and spinal accessory nerves, and internally to the jugular vein. It then passes forwards between the jugular vein and internal carotid artery, to the stylo-pharyngeus muscle, and descends along the inferior border of that muscle to the hyo-glossus, beneath which it curves to be distributed to the mucous membrane of the base of the tongue and fauces, to the mucous glands of the mouth, and to the tonsils. While situated in the jugular fossa, the nerve presents two gangliform swellings; one superior (ganglion jugulare of Müller) of small size, and involving only the posterior fibres of the nerve; the other inferior, nearly half an inch below the preceding, of larger size and occupying the whole diameter of the nerve, the ganglion of Andersch* (ganglion petrosum).

The fibres of origin of this nerve may be traced through the fasciculi of the corpus restiforme to the grey substance in the floor of the fourth ventricle.

The Branches of the glosso-pharyngeal nerve are—

Communicating branches with the Facial,

Pneumogastric,

Spinal accessory,

Sympathetic.

Tympanic,

Muscular,

Pharyngeal,

Lingual,

Tonsillitic.

The Branches of communication proceed from the ganglion and from the upper part of the trunk of the nerve, and are common to the facial, eighth pair, and sympathetic; they form a complicated plexus at the base of the skull.

The Tympanic branch (Jacobson’s nerve) proceeds from the ganglion of Andersch, or from the trunk of the nerve immediately above the ganglion: it enters a small bony canal in the jugular fossa (page 34) and divides into six branches, which are distributed upon the inner wall of the tympanum, and establish a plexiform communication (tympanic plexus) with the sympathetic and fifth pair of nerves. The branches of distribution supply the fenestra rotunda, fenestra ovalis, and Eustachian tube: those of communication join the carotid plexus, the petrosal branch of the Vidian nerve, and the otic ganglion.

* Charles Samuel Andersch. "Tractatus Anatomico-Physiologicus de Nervis Corporis Humani Aliquibus, 1797."
The Muscular branch divides into filaments, which are distributed to the stylo-pharyngeus and to the posterior belly of the digastricus and stylo-hyoideus muscle.

The Pharyngeal branches are two or three filaments which are distributed to the pharynx and unite with the pharyngeal branches of the pneumogastric and sympathetic nerve to form the pharyngeal plexus.

The Lingual branches enter the substance of the tongue beneath the hyo-glossus and stylo-glossus muscle, and are distributed to the mucous membrane of the side and base of the tongue, and to the epiglottis and fauces.

The Tonsillar branches proceed from the glosso-pharyngeal nerve near its termination; they form a plexus (circulus tonsillaris) around the base of the tonsil, from which numerous filaments are given off to the mucous membrane of the fauces and soft palate, communicating with the posterior palatine branches of Meckel's ganglion.

Pneumogastric Nerve (vagus).—The pneumogastric nerve arises by ten or fifteen filaments from the groove between the corpus olivare and corpus restiforme, immediately below the glosso-pharyngeal, and passes out of the skull through the inner extremity of the jugular foramen in a distinct canal of the dura mater. While situated in this canal it presents a small rounded ganglion (ganglion jugulare); and having escaped from the skull, a gangliform swelling (plexus gangliformis), nearly an inch in length, and surrounded by an irregular plexus of white nerves, which communicate with each other, with the other divisions of the eighth pair, and with the trunk of the pneumogastric below the ganglion. The plexus gangliformis (ganglion of the superior laryngeal branch, of Sir Astley Cooper), is situated, at first, behind the internal carotid artery, and then between that vessel and the internal jugular vein. The pneumogastric nerve then descends the neck within the sheath of the carotid vessels, lying behind and between the artery and vein, to the root of the neck. Here the course of the nerve at opposite sides becomes different.

On the right side it passes between the subclavian artery and vein to the posterior mediastinum, then behind the root of the lung to the oesophagus, which it accompanies to the stomach, lying on its posterior aspect.

On the left it enters the chest parallel with the left subclavian artery, crosses the arch of the aorta, and descends behind the root of the lung, and along the anterior surface of the oesophagus, to the stomach.

The fibres of origin of the pneumogastric nerve, like those of the glosso-pharyngeal, may be traced through the fasciculi of the corpus restiforme into the grey substance of the floor of the fourth ventricle.
The Branches of the pneumogastric nerve are the following:

Communicating branches with the Facial,

Glosso-pharyngeal,
Spinal accessory,
Hypo-glossal,
Sympathetic.

Auricular,
Pharyngeal,
Superior laryngeal,
Cardiac,
Inferior or recurrent laryngeal,
Pulmonary anterior,
Pulmonary posterior,
Oesophageal,
Gastric.

The Branches of communication form part of the complicated plexus at the base of the skull. The branches to the ganglion of Andersch are given off by the superior ganglion in the jugular fossa.

The Auricular nerve is given off from the lower part of the jugular ganglion, or from the trunk of the nerve immediately below, and receives immediately after its origin a small branch of communication from the glossopharyngeal. It then passes outwards behind the jugular vein, and on the outer side of that vessel enters a small canal (page 34) in the petrous portion of the temporal bone near the stylo-mastoid foramen. Guided by this canal it reaches the descending part of the aqueductus Fallopii and joins the facial nerve. In the aqueductus Fallopii the auricular nerve gives off two small filaments, one of which communicates with the posterior auricular branch of the facial, while the other is distributed to the pinna.

The Pharyngeal nerve arises from the pneumogastric, immediately above the gangliform plexus, and descends behind the internal carotid artery to the upper border of the middle constrictor, upon which it forms the pharyngeal plexus assisted by branches from the glossopharyngeal, superior laryngeal, and sympathetic. The pharyngeal plexus is distributed to the muscles and mucous membrane of the pharynx.

The Superior laryngeal nerve arises from the gangliform plexus of the pneumogastric, of which it appears to be almost a continuation; hence this plexus was named by Sir Astley Cooper the "ganglion of the superior laryngeal branch." The nerve descends behind the internal carotid artery to the opening in the thyro-hyoidean membrane, through which it passes with the superior laryngeal artery, and is distributed to the mucous membrane of the larynx and arytenoideus muscle. On the latter, and behind the cricoid cartilage, it communicates with the recurrent laryngeal nerve. Behind the internal carotid it gives off the external laryngeal branch, which sends a twig
to the pharyngeal plexus, and then descends to supply the inferior constrictor and crico-thyroid muscles and thyroid gland. This branch communicates inferiorly with the recurrent laryngeal and sympathetic nerve.

Mr. Hilton of Guy's Hospital, concludes from his dissections† that the superior laryngeal nerve is the nerve of sensation to the larynx, being distributed solely (with the exception of its external laryngeal branch and a twig to the arytenoides) to the mucous membrane. If this fact be taken in connection with the observations of Sir Astley Cooper, and the dissections of the origin of the nerve by Mr. Edward Cock, we shall have ample evidence, both in the ganglionic origin of the

† Guy's Hospital Reports, vol. ii.
nerve and in its distribution, of its sensitive function. The recurrent, or inferior laryngeal nerve, is the proper motor nerve of the larynx, and is distributed to its muscles.

The Cardiac branches, two or three in number, arise from the pneumogastric in the lower part of the neck, and cross the lower part of the common carotid, to communicate with the cardiac branches of the sympathetic, and with the great cardiac plexus.

The Recurrent laryngeal, or inferior laryngeal nerve, curves around the subclavian artery on the right, and the arch of the aorta on the left side. It ascends in the groove between the trachea and oesophagus, and piercing the lower fibres of the inferior constrictor muscle enters the larynx close to the articulation of the inferior cornu of the thyroid with the cricoid cartilage. It is distributed to all the muscles of the larynx, with the exception of the crico-thyroid, and communicates on the arytenoideus muscle with the superior laryngeal nerve. As it curves around the subclavian artery and aorta it gives branches to the heart and root of the lungs; and as it ascends the neck it distributes filaments to the oesophagus and trachea, and communicates with the external laryngeal nerve and sympathetic.

The Anterior pulmonary branches are distributed upon the anterior aspect of the root of the lungs, forming, with branches from the great cardiac plexus, the anterior pulmonary plexus.

The Posterior pulmonary branches, more numerous than the anterior, are distributed upon the posterior aspect of the root of the lungs, and are joined by branches from the great cardiac plexus, forming the posterior pulmonary plexus.

Upon the oesophagus the two nerves divide into numerous branches which communicate with each other and constitute the oesophageal plexus which completely surrounds the cylinder of the oesophagus, and accompanies it to the cardiac orifice of the stomach.

The Gastric branches are the terminal filaments of the two pneumogastric nerves; they are spread out upon the anterior and posterior surfaces of the stomach, and are likewise distributed to the omentum, spleen, pancreas, liver, and gall-bladder, and communicate, particularly the right nerve, with the solar plexus.

Spinal Accessory Nerve.—The spinal accessory nerve arises by several filaments from the side of the spinal cord as low down as the fourth or fifth cervical nerve, and ascends behind the ligamentum denticulatum, and between the anterior and posterior roots of the spinal nerves, to the foramen lacerum posterius. It communicates in its course with the posterior root of the first cervical nerve, and entering the foramen lacerum becomes applied against the posterior aspect of the ganglion jugulare of the pneumogastric, being contained in the same sheath of dura mater. In the jugular fossa it divides into two branches; the smaller joins the pneumogastric immediately below the jugular ganglion, and contributes to the formation of the pharyngeal nerve; the larger or true continuation of the nerve passes backwards
behind the internal jugular vein, and descends obliquely to the upper part of the sterno-mastoid muscle. It pierces the sterno-mastoid, and

* The anatomy of the side of the neck, shewing the nerves of the tongue. 1. A fragment of the temporal bone containing the meatus auditorius externus, mastoid, and styloid process. 2. The stylo-hyoid muscle. 3. The stylo-glossus. 4. The stylo-pharyngeus. 5. The tongue. 6. The hyo-glossus muscle; its two portions. 7. The genio-hyo-glossus muscle. 8. The genio-hyoidicus; they both arise from the inner surface of the symphysis of the lower jaw. 9. The sterno-hyoid muscle. 10. The sterno-thyroid. 11. The thyro-hyoidean, upon which the thyro-hyoidean branch of the hypoglossal nerve is seen ramifying. 12. The omo-hyoid, crossing the common carotid artery (13), and internal jugular vein (14). 15. The external carotid giving off its branches. 16. The internal carotid. 17. The gustatory nerve giving off a branch to the submaxillary ganglion (18), and communicating a little further on with the hypoglossal nerve. 19. The submaxillary, or Wharton's duct, passing forwards to the sublingual gland. 20. The glosso-pharyngeal nerve, passing in behind the hyo-glossus muscle. 21. The hypoglossal nerve curving around the occipital artery. 22. The descendens noni nerve, forming a loop with (23) the communicans noni, which is seen to be arising by filaments from the upper cervical nerves. 24. The pneumogastric nerve, emerging from between the internal jugular vein and common carotid artery, and entering the chest. 25. The facial nerve, emerging from the stylo-mastoid foramen, and crossing the external carotid artery.
then passes obliquely across the neck, communicating with the second, third, and fourth cervical nerves, and is distributed to the trapezius. The spinal accessory sends numerous twigs to the sterno-mastoid in its passage through that muscle, and in the trapezius the nervous filaments may be traced downwards to its lower border.

The pneumogastric and spinal accessory nerves together (nervus vagus cum accessorio) resemble a spinal nerve, of which the former with its ganglion is the posterior and sensitive root, the latter the anterior and motor root.

Ninth pair.* Hypoglossal nerve (lingual). The hypoglossal nerve arises from the groove between the corpus pyramidale and corpus olivare by ten or fifteen filaments, which being collected into two bundles, escape from the cranium through the anterior condyloid foramen. The nerve then passes forwards between the internal carotid artery and internal jugular vein, and descends along the anterior and inner side of the vein to a point parallel with the angle of the lower jaw. It next curves inwards around the occipital artery, with which it forms a loop, and crossing the lower part of the hypoglossus muscle to the genio-hyo-glossus, sends filaments onwards with the anterior fibres of that muscle as far as the tip of the tongue. It is distributed to the muscles of the tongue, and principally to the genio-hyo-glossus. While resting on the hypo-glossus muscle it is flattened, and beneath the mylo-hyoideus it communicates with the gustatory nerve.

At its origin the hypoglossal nerve sometimes communicates with the posterior root of the first cervical nerve.

The Branches of the hypoglossal nerve are:—

Communicating branches with the Pneumogastric,
Spinal accessory,
First and second cervical nerves,
Sympathetic.

Descendens noni,
Thyro-hyoidean branch,
Communicating filaments with the gustatory nerve.

The Communications with the pneumogastric and spinal accessory take place through the medium of a plexiform interlacement of branches at the base of the skull, behind the internal jugular vein. The communications with the sympathetic nerve are derived from the superior cervical ganglion.

The Descendens noni is a long and slender twig, which quits the hypoglossal just as that nerve is about to form its arch around the occipital artery, and descends upon the sheath of the carotid vessels. Just below the middle of the neck it forms a loop with a long branch

* The twelfth pair according to the arrangement of Soemmering.
(communicans noni) from the second and third cervical nerves. From the convexity of this loop branches are sent to the sterno-hyoideus, sterno-thyroideus, and both bellies of the omo-hyoideus; sometimes also a twig is given off to the cardiac plexus, and occasionally one to the phrenic nerve. If the descendens noni be traced to its origin it will be found to be formed by a branch from the hypoglossal, and one from the first and second cervical nerves; occasionally it receives also a filament from the pneumogastric.

The Thyro-hyoidean nerve is a small branch, distributed to the thyro-hyoideus muscle. It is given off from the trunk of the hypoglossal near the posterior border of the hyoglossus muscle, and descends obliquely over the great cornu of the os hyoides.

The Communicating filaments, with the gustatory nerve, are several small twigs, which ascend upon the hyoglossus muscle near its anterior border, and form a kind of plexus with filaments sent down by the gustatory nerve.

**SPINAL NERVES.**

There are thirty-one pairs of spinal nerves, each arising by two roots, an anterior or motor root, and a posterior or sensitive root.

The anterior roots proceed from a narrow white line, anterior lateral sulcus, on the antero-lateral column of the spinal cord, and gradually approach towards the anterior longitudinal fissure as they descend.

The posterior roots, more regular than the anterior, proceed from the posterior lateral sulcus, a narrow grey stria, formed by the internal grey substance of the cord. They are larger, and the filaments of origin more numerous than those of the anterior roots. In the intervertebral foramina there is a ganglion on each of the posterior roots. The first cervical nerve forms an exception to these characters; its posterior root is smaller than the anterior; it often joins in whole or in part with the spinal accessory nerve and sometimes with the hypoglossal: there is frequently no ganglion upon it, and when the ganglion exists it is often situated within the dura mater, the latter being the usual position of the ganglia of the last two pairs of spinal nerves.

After the formation of a ganglion, the two roots unite and constitute a spinal nerve, which escapes through the intervertebral foramen and divides into an anterior branch for the supply of the front aspect of the body, and a posterior branch for the posterior aspect. In the first cervical and two last sacral nerves this division takes place within the dura mater and in the upper four sacral nerves externally to that cavity, but within the sacral canal. The anterior branches, with the exception of the first two cervical nerves, are larger than the posterior; an arrangement which is proportioned to the larger extent of surface they are required to supply.
The Spinal nerves are divided into—

<table>
<thead>
<tr>
<th>Cervical</th>
<th>Dorsal</th>
<th>Lumbar</th>
<th>Sacral</th>
</tr>
</thead>
<tbody>
<tr>
<td>8 pairs</td>
<td>12</td>
<td>5</td>
<td>6</td>
</tr>
</tbody>
</table>

The cervical nerves pass off transversely from the spinal cord; the dorsal are oblique in their direction; and the lumbar and sacral vertical; the latter form the large assemblage of nerves at the termination of the cord called cauda equina.

CERVICAL NERVES.

The cervical nerves increase in size from above downwards; the first (sub-occipital) passes out of the spinal canal between the occipital bone and the atlas; and the last, between the last cervical and first dorsal vertebra. Each nerve, at its escape from the intervertebral foramen, divides into an anterior and a posterior branch. The anterior branches of the four upper cervical nerves form the cervical plexus; the posterior branches, the posterior cervical plexus. The anterior branches of the four inferior cervical together with the first dorsal form the brachial plexus.

Anterior Cervical Nerves.—The anterior branch of the first cervical nerve escapes from the vertebral canal through the groove upon the posterior arch of the atlas which supports the vertebral artery, beneath which it lies. It then descends in front of the transverse process of the atlas, sends several twigs to the rectus lateralis and recti antici, and forms an anastomotic loop by communicating with an ascending branch of the second nerve.

The anterior branch of the second cervical nerve at its exit from the intervertebral foramen between the atlas and the axis, gives twigs to the rectus anticus major, scalenus posticus and levator anguli scapulae muscles and divides into three branches, viz. an ascending branch, which completes the arch of communication with the first nerve; and two descending branches, which communicate with the third nerve.

The anterior branch of the third cervical nerve, double the size of the preceding, divides at its exit from the intervertebral foramen into numerous branches, some of which are distributed to the rectus major, longus colli, and scalenus posticus muscles, while others communicate and form loops and anastomoses with the second and fourth nerve.

The anterior branch of the fourth cervical nerve, of the same size with the preceding, sends twigs to the rectus major, longus colli, and levator anguli scapulae, communicates by anastomosis with the third, and sends a small branch downwards to the fifth nerve. Its principal branches pass downwards and outwards across the posterior triangle of the neck, towards the clavicle and acromion.
The anterior branches of the fifth, sixth, seventh, and eighth cervical nerves will be described with the brachial plexus, of which they form a part.

CERVICAL PLEXUS.

The cervical plexus is constituted by the loops of communication, and by the anastomoses which take place between the anterior branches of the four first cervical nerves. The plexus rests upon the levator anguli scapulae, posterior scalenus, and splenius muscle, and is covered in by the sterno-mastoid and platysma.

The Branches of the cervical plexus may be arranged into three groups, superficial ascending, superficial descending; and deep—

\[
\begin{align*}
\text{Superficial} & \quad \{ \text{Ascending,} & \quad \{ \text{Superficialis colli,} \\
& \quad \{ \text{Ascending,} & \quad \{ \text{Auricularis magnus,} \\
& \quad \{ \text{Descending,} & \quad \{ \text{Occipitalis minor.} \\
& \quad \{ \text{Communicating branches,} & \quad \{ \text{Acromiales,} \\
\text{Deep} & \quad \{ \text{Muscular,} & \quad \{ \text{Claviculares.} \\
& \quad \{ \text{Communicans noni,} & \quad \{ \text{Phrenic.} \\
\end{align*}
\]

The Superficialis colli is formed by communicating branches from the second and third cervical nerves; it curves around the posterior border of the sterno-mastoid and crosses obliquely behind the external jugular vein to the anterior border of that muscle, where it divides into an ascending and a descending branch; the descending branch is distributed to the integument on the side and front of the neck, as low down as the clavicle; the ascending branch passes upwards to the submaxillary region, and divides into four or five filaments, some of which pierce the platysma myoides and supply the integument as high up as the chin and the lower part of the face, while others form a plexus with the descending branches of the facial nerve beneath the platysma. One or two filaments from this nerve accompany the external jugular vein.

The Auricularis magnus, the largest of the three ascending branches of the cervical plexus, also proceeds from the second and third cervical nerve; it curves around the posterior border of the sterno-mastoid and ascends upon that muscle, lying parallel with the external jugular vein, to the parotid gland, where it divides into an anterior and a posterior branch. The anterior branch is distributed to the integument over the parotid gland, to the gland itself, communicating with the facial nerve, and to the external ear. The posterior branch pierces the parotid gland and crosses the mastoid process, where it divides into branches which supply the posterior part of the pinna and the integument of the side of the head, and communicate with the posterior auricular
branch of the facial and with the occipitalis minor. Previously to its division the auricularis magnus nerve sends off several facial branches which are distributed to the cheek.

The *Occipitalis minor* arises from the second cervical nerve; it curves around the posterior border of the sterno-mastoid above the preceding and ascends upon that muscle, parallel with its posterior border, to the lateral and posterior side of the head. It is distributed to the integument and to the muscles of this region, namely, to the occipito-frontalis, attollens and attrahens aurem, and communicates with the occipitalis major, auricularis magnus and posterior auricular branch of the facial.

The *Acromiales* and *Claviculares* are two or three large nerves which proceed from the fourth cervical nerve and divide into numerous branches which pass downwards over the clavicle, and are distributed to the integument of the upper and anterior part of the chest from the sternum to the shoulder.

The *Communicating branches* are filaments which arise from the loop between the first and second cervical nerve, and pass inwards to communicate with the sympathetic, the pneumogastric, and the hypoglossal nerve. The three first cervical nerves send branches to the first cervical ganglion; the fourth sends a branch to the trunk of the sympathetic, or to the middle cervical ganglion. From the second cervical nerve a large branch is given off which goes to join the spinal accessory nerve.

The *Muscular branches* proceed from the third and fourth cervical nerves; they are distributed to the trapezius, levator anguli scapulae, and rhomboidei muscles.

The *Communicans noni* is a long slender branch formed by filaments from the first, second, and third cervical nerves: it descends upon the outer side of the internal jugular vein, and forms a loop with the descendens noni over the sheath of the carotid vessels.

The *Phrenic nerve* (internal respiratory of Bell) is formed by filaments from the third, fourth, and fifth cervical nerves, receiving also a branch from the sympathetic. It descends to the root of the neck, resting upon the scalenus anticus muscle, then crosses the first portion of the subclavian artery, and enters the chest between it and the subclavian vein. Within the chest it passes through the middle mediastinum, between the pleura and pericardium, and in front of the root of the lung to the diaphragm to which it is distributed, some of its filaments reaching the abdomen through the openings for the oesophagus and vena cava, and communicating with the phrenic and solar plexus, and on the right side with the hepatic plexus. The left phrenic nerve is rather longer than the right, from the inclination of the heart to the left side.

**Posterior cervical nerves.**—The posterior division of the *first cervical nerve* (sub-occipital), larger than the anterior, escapes from the vertebral canal through the opening for the vertebral artery, lying
posteriorly to that vessel, and emerges into the triangular space formed by the rectus posticus major, obliquus superior, and obliquus inferior. It is distributed to the recti and obliqui muscles, and sends one or two filaments downwards to communicate with the second cervical nerve. The posterior branch of the *second cervical nerve* is three or four times greater than the anterior branch, and is larger than the other posterior cervical nerves. The posterior branch of the *third cervical nerve* is smaller than the preceding, but larger than the fourth; and the other posterior cervical nerves go on progressively decreasing to the seventh. The posterior branches of the fourth, fifth, sixth, seventh, and eighth nerves pass inwards between the muscles of the back in the cervical and upper part of the dorsal region, and reaching the surface near the middle line, are reflected outwards, to be distributed to the integument. The fourth and fifth are nearly transverse in their course, and lie between the semispinalis colli and complexus. The sixth, seventh, and eighth are directed nearly vertically downwards; they pierce the aponeurosis of origin of the splenius and trapezius.

**Posterior Cervical Plexus.**—This plexus is constituted by the succession of anastomosing loops and communications which pass between the posterior branches of the first, second, and third cervical nerves. It is situated between the complexus and semispinalis colli, and its branches are the—

*Musculo-cutaneous,*

*Occipitalis major.*

The *Musculo-cutaneous* branches pass inwards between the complexus and semispinalis colli to the ligamentum nuchae, distributing muscular filaments in their course. They then pierce the aponeurosis of the trapezius and become subcutaneous, sending branches outwards to supply the integument of the posterior aspect of the neck, and upwards to the posterior region of the scalp.

The *Occipitalis major* is the direct continuation of the second cervical nerve; it ascends obliquely inwards, between the obliquus inferior and complexus, pierces the complexus and trapezius after passing for a short distance between them, and ascends upon the posterior aspect of the head between the integument and occipito-frontalis, in company with the occipital artery. The occipitalis major sends numerous branches to the muscles of the neck, and is distributed to the integument of the scalp, as far forwards as the middle of the vertex of the head. Its branches communicate with those of the occipitalis minor.

**Brachial Plexus.**

The *Brachial or axillary plexus* of nerves is formed by communications between the anterior branches of the four last cervical and first dorsal nerve. These nerves are all similar in size, and their mode of
disposition in the formation of the plexus is the following: the fifth and sixth nerves unite to form a common trunk, which soon divides into two branches; the last cervical and first dorsal also unite immediately upon their exit from the intervertebral foramina, and the common trunk resulting from their union after a short course also divides into two branches; the seventh nerve passes outwards between the common trunks of the two preceding, and opposite the clavicle divides into a superior branch which unites with the inferior division of the superior trunk, and an inferior branch which communicates with the superior division of the inferior trunk: from these divisions and communications the brachial plexus results. The brachial plexus communicates with the cervical plexus by means of a branch sent down from the fourth to the fifth nerve, and by the inferior branch of origin of the phrenic nerve, and also sends filaments of communication to the sympathetic. The plexus is broad in the neck, narrows as it descends into the axilla, and again enlarges at its lower part where it divides into its six terminal branches.

**Relations.**—The brachial plexus is in relation in the neck with the two scaleni muscles, between which its nerves issue; lower down it is placed between the clavicle and subclavius muscle above, and the first rib and first serration of the serratus magnus muscle below. In the axilla, it is situated at first to the outer side and then behind the axillary artery, resting by its outer border against the tendon of the subscapularis muscle. At this point it completely surrounds the artery by means of the two cords which are sent off to form the median nerve.

Its *Branches* may be arranged into two groups, humeral and descending,—

**Humeral Branches.**
- Superior muscular,
- Short thoracic,
- Long thoracic,
- Supra-scapular,
- Subscapular,
- Inferior muscular.

**Descending Branches.**
- External cutaneous,
- Internal cutaneous,
- Lesser internal cutaneous,
- Median,
- Ulnar,
- Musculo-spiral,
- Circumflex.

The superior *Muscular nerves* are several large branches which are given off by the fifth cervical nerve above the clavicle; they are, a subclavian branch to the subclavius muscle, which usually sends a communicating filament to the phrenic nerve; a rhomboïd branch to the rhomboidei muscles; and frequently an angular branch to the levator anguli scapule.

The *Short thoracic nerves* (anterior) are two in number; they arise from the brachial plexus at a point parallel with the clavicle, and are divisible into an anterior and a posterior branch. The anterior branch passes forwards between the subclavius muscle and the subclavian vein, and is distributed to the pectoralis major muscle, entering it by
its costal surface. In its course it sends one or two twigs to the deltoid muscle and gives off a branch which forms a loop of communication with the posterior branch. The posterior branch passes forward beneath the axillary artery and unites with the communicating branch of the preceding to form a loop, from which numerous branches are given off to the pectoralis major and pectoralis minor.

The Long thoracic nerve (posterior thoracic, external respiratory of Bell) is a long and remarkable branch arising from the fourth and fifth cervical nerves, immediately after their escape from the intervertebral foramina. It passes down behind the plexus and axillary vessels, resting on the scalenus posticus muscle; it then descends along the side of the chest upon the serratus magnus muscle to its lowest serration. It sends numerous filaments to this muscle in its course.

The Supra-scapular nerve arises above the clavicle from the fifth cervical nerve and descends obliquely outwards to the supra-scapular notch; it then passes through the notch, crosses the supra-spinous fossa beneath the supra-spinatus muscle, and passing in front of the concave margin of the spine of the scapula enters the infra-spinous fossa. It is distributed to the supra-spinatus and infra-spinatus muscle.

The Subscapular nerves are two in number; of which one arises from the brachial plexus above the clavicle, the others from the posterior aspect of the plexus within the axilla. They are distributed to the subscapularis muscle.

The Inferior muscular nerves are two or three branches which proceed from the lower and back part of the brachial plexus, and are distributed to the latissimus dorsi and teres major. The former of these is the longer, and follows the course of the subscapular artery.

The terminal branches of the plexus are arranged in the following order: the external cutaneous, and one head of the median to the outer side of the artery; the other head of the median, internal cutaneous, lesser internal cutaneous, and ulnar, upon its inner side; and the circumflex and musculo-spiral behind.

The External cutaneous nerve (musculo-cutaneous, perforans Casserii) arises from the brachial plexus in common with the external head of the median; it pierces the coraco-brachialis muscle and passes between the biceps and brachialis anticus, to the outer side of the bend of the elbow, where it perforates the fascia, and divides into an external and internal branch. The branches pass behind the median cephalic vein, the external, the larger of the two, taking the course of the radial vein and communicating with the branches of the radial nerve on the back of the hand; the internal and smaller following the direction of the supinator longus, communicating with the internal cutaneous, and at the lower third of the fore-arm sending off a twig, which accompanies the radial artery to the wrist, and distributes filaments to the synovial membranes of the joint.

The external cutaneous nerve supplies the coraco-brachialis, biceps
and brachialis anticus in the upper arm, and the integument of the outer side of the fore-arm as far as the wrist and hand.

The **internal cutaneous nerve** is one of the internal and smaller of the branches of the axillary plexus; it arises from the plexus in common with the ulnar and internal head of the median, and passes down the inner side of the arm in company with the basilic vein, giving off several cutaneous filaments in its course. At about the middle of the upper arm it pierces the deep fascia by the side of the basilic vein and divides into two branches, anterior and posterior. The **anterior** branch, the larger of the two, divides into several branches which pass in front of, and sometimes behind, the median basilic vein at the bend of the elbow, and descend in the course of the palmaris longus muscle to the wrist, distributing filaments to the integument in their course and communicating with the anterior branch of the external cutaneous on the outer side, and its own posterior branch on the inner side of the fore-arm. The **posterior** branch sends off several twigs to the integument over the inner condyle and olecranon, and then descends the fore-arm in the course of the ulnar vein as far as the wrist, supplying the integument on the inner side of the fore-arm and communicating with the anterior branch of the same nerve in front, and the dorsal branch of the ulnar nerve on the wrist.

The external cutaneous nerve. 8. The point at which it pierces the coraco-brachialis muscle. 9. The internal cutaneous nerve: the point at which it pierces the deep fascia. 10. The origin of the median nerve by two heads. 11. The bend of the elbow where the median
The Lesser internal cutaneous nerve or nerve of Wrisberg, the smallest of the branches of the brachial plexus, is very irregular in point of origin. It is a long and slender nerve, and usually arises from the common trunk of the last cervical and first dorsal nerve. Passing downwards into the axillary space it communicates with the external branch of the first intercosto-humeral nerve, and descends on the inner side of the internal cutaneous nerve, to the middle of the posterior aspect of the upper arm, where it pierces the fascia and is distributed to the integument of the elbow, communicating with filaments of the posterior branch of the internal cutaneous and with the spiral cutaneous. In its course it gives off two or three cutaneous filaments to the integument of the inner and anterior aspect of the upper arm.

The Median nerve has received its name from taking a course along the middle of the fore-arm to the palm of the hand; it is, therefore, intermediate in position between the radial and ulnar nerves. It commences by two heads, which embrace the axillary artery; lies at first to the outer side of the brachial artery, which it crosses at its middle; and descends on its inner side to the bend of the elbow. It then passes between the two heads of the pronator radii teres and flexor sublimis digitorum muscles, and runs down the fore-arm, between the flexor sublimis and profundus, and beneath the annular ligament, into the palm of the hand.

The Branches of the median nerve are,—

Muscular,  Superficial palmar,
Anterior interosseous,  Digital.

The Muscular branches are given off by the nerve at the bend of the elbow; they are distributed to all the muscles on the anterior aspect of the fore-arm, with the exception of the flexor carpi ulnaris, and to the periosteum. The branch to the pronator radii teres sends off reflected branches to the elbow-joint.

The Anterior interosseous is a large branch accompanying the anterior interosseous artery, and supplying the deep layer of muscles in the fore-arm. It passes beneath the pronator quadratus muscle, and pierces the interosseous membrane near the wrist. On reaching the
posterior aspect of the wrist it joins a large and remarkable ganglion, which gives off a number of branches for the supply of the joint.

The Superficial palmar branch arises from the median nerve at about the lower fourth of the fore-arm: it crosses the annular ligament, and is distributed to the integument over the ball of the thumb and in the palm of the hand.

The median nerve at its termination in the palm of the hand is spread out and flattened, and divides into six branches, one muscular and five digital. The muscular branch is distributed to the muscles of the ball of the thumb. The digital branches send twigs to the lumbricales muscles and are thus arranged: two pass outwards to the thumb to supply its borders; one to the radial side of the index finger; one subdivides for the supply of the adjoining sides of the index and middle fingers; and the remaining one, for the supply of the adjoining sides of the middle and ring fingers. The digital nerves in their course along the fingers are situated to the inner side of the digital arteries. Opposite the base of the first phalanx each nerve gives off a dorsal branch which runs along the border of the dorsum of the finger. Near the extremity of the finger the digital nerve divides into a palmar and a dorsal branch; the former supplying the sentient extremity of the finger, and the latter the structures around and beneath the nail. The digital nerve maintains no communication with its fellow of the opposite side.

The Ulnar nerve is somewhat smaller than the median, behind which it lies, gradually diverging from it in its course. It arises from the brachial plexus in common with the internal head of the median and the internal cutaneous nerve, and runs down the inner side of the arm, to the groove between the internal condyle and olecranon, resting upon the internal head of the triceps, and accompanied by the inferior profunda artery. At the elbow it is superficial, and supported by the inner condyle, against which it is easily compressed, giving rise to the thrilling sensation along the inner side of the fore-arm and little finger, ascribed to striking the "funny bone." It then passes between the two heads of the flexor carpi ulnaris and descends along the inner side of the fore-arm, crosses the annular ligament, and divides into two branches, superficial and deep palmar. At the commencement of the middle third of the fore-arm, it becomes applied against the artery, and lies to its ulnar side, as far as the hand.

The Branches of the ulnar nerve are,—

Muscular in the upper arm, Dorsal branch,
Articular, Superficial palmar,
Muscular in the fore-arm, Deep palmar,
Anastomotic,

The Muscular branches in the upper arm are a few filaments distributed to the triceps.
The **Articular branches** are several filaments to the elbow-joint, which are given off from the nerve as it lies in the groove between the inner condyle and the olecranon.

The **Muscular branches** in the fore-arm are distributed to the flexor carpi ulnaris and flexor profundus digitorum muscle.

The **Anastomotic branch** (n. cutaneus palmaris ulnaris) is a small nerve which arises from the ulnar at about the middle of the fore-arm, and divides into a deep and a superficial branch; the former accompanies the ulnar artery, the latter pierces the deep fascia and is distributed to the integument, communicating with the posterior branch of the internal cutaneous nerve.

The **Dorsal branch** passes backwards beneath the tendon of the flexor carpi ulnaris, at the lower third of the fore-arm, and divides into branches which supply the integument and two fingers and a half on the posterior aspect of the hand, communicating with the internal cutaneous and radial nerve.

The **Superficial palmar branch** divides into three filaments, which are distributed, one to the ulnar side of the little finger, one to the adjoining borders of the little and ring fingers, and a communicating branch to join the median nerve.

The **Deep palmar branch** passes between the abductor and flexor minimi digiti, to the deep palmar arch, supplying the muscles of the little finger, and the interossei and other deep structures in the palm of the hand.

The **Musculo-spiral nerve**, the largest branch of the brachial plexus, arises from the posterior part of the plexus by a common trunk with the circumflex nerve. It passes downwards from its origin in front of the tendons of the latissimus dorsi and teres major muscle, and winds around the humerus in the spiral groove, accompanied by the superior profunda artery, to the space between the brachialis anticus and supinator longus, and thence onwards to the bend of the elbow, where it divides into two branches, the posterior interosseous and radial nerve.

The **Branches** of the musculo-spiral nerve are,—

Muscular,
Spiral cutaneous,
Radial,
Posterior interosseous.

The **Muscular branches** are distributed to the triceps, to the supinator longus, and to the extensor carpi radialis longior.

The **Spiral cutaneous nerve** pierces the deep fascia immediately below the insertion of the deltoid muscle, and passes down the outer side of the fore-arm as far as the wrist. It is distributed to the integument.

The **Radial nerve** runs along the radial side of the fore-arm to the
commencement of its lower third; it then passes beneath the tendon of the supinator longus, and at about two inches above the wrist-joint pierces the deep fascia and divides into an external and an internal branch. The external branch, the smaller of the two, is distributed to the outer border of the hand and thumb, and communicates with the posterior branch of the external cutaneous nerve. The internal branch crosses the direction of the extensor tendons of the thumb and divides into several filaments for the supply of the ulnar border of the thumb, the radial border of the index finger, and the adjoining borders of the index and middle fingers. It communicates on the back of the hand with the dorsal branch of the ulnar nerve.

In the upper third of the fore-arm the radial nerve lies beneath the border of the supinator longus muscle. In the middle third it is in relation with the radial artery lying to its outer side. It then quits the artery, and passes beneath the tendon of the supinator longus, to reach the back of the hand.

The Posterior interosseous nerve, somewhat larger than the radial, separates from the latter at the bend of the elbow, pierces the supinator brevis muscle, and emerges from its lower border on the posterior aspect of the fore-arm, where it divides into branches which supply the whole of the muscles on the posterior aspect of the fore-arm. One branch, longer than the rest, descends to the posterior part of the wrist, and forms a large gangliform swelling (the common character of nerves which supply joints), from which numerous branches are distributed to the wrist-joint.

The Circumflex nerve arises from the posterior part of the brachial plexus by a common trunk with the musculo-spiral nerve. It passes downwards over the border of the subscapularis muscle, winds around the neck of the humerus with the posterior circumflex artery, and terminates by dividing into numerous branches which supply the deltoïd muscle.

The Branches of the circumflex nerve are muscular and cutaneous. The Muscular branches are distributed to the subscapularis, teres minor, teres major, latissimus dorsi, and deltoïd. The cutaneous branches pierce the deltoïd muscle and are distributed to the integument of the shoulder. One of these cutaneous branches (cutaneus brachii superior), larger than the rest, winds around the posterior border of the deltoïd, and divides into filaments which pass in a radiating direction across the shoulder and are distributed to the integument.

DORSAL NERVES.

The dorsal nerves are twelve in number on each side; the first appears between the first and second dorsal vertebrae, and the last between the twelfth dorsal and first lumbar. They are smaller than the lower cervical nerves, and diminish gradually in size from the first
to the tenth, and then increase to the twelfth. Each nerve, as soon as it has escaped from the intervertebral foramen, divides into two branches; a dorsal branch and the true intercostal nerve.

The Dorsal branches pass directly backwards between the transverse processes of the vertebrae, lying internally to the anterior costotransverse ligament, where each nerve divides into an anterior or muscular and a posterior or musculo-cutaneous branch. The muscular branch enters the substance of the muscles in the direction of a line corresponding with the interval of separation between the longissimus dorsi and sacro-lumbalis, and is distributed to the muscles of the back, its terminal filaments reaching to the integument. The musculo-cutaneous branch passes inwards, crossing the semispinalis dorsi to the spinous processes of the dorsal vertebrae, giving off muscular branches in its course; it then pierces the aponeurosis of origin of the trapezius and latissimus dorsi, and divides into branches which are inclined outwards beneath the integument to which they are distributed.

The dorsal branch of the first dorsal nerve resembles in its mode of distribution the dorsal branches of the last cervical. The dorsal branches of the last four dorsal nerves pass obliquely downwards and outwards into the substance of the erector spinae in the situation of the interspace between the sacro-lumbalis and longissimus dorsi. After supplying the erector spinae and communicating freely with each other they approach the surface along the outer border of the sacro-lumbalis, where they pierce the aponeuroses of the transversalis, internal oblique, serratus posticus inferior, and latissimus dorsi, and divide into internal branches which supply the integument in the lumbar region upon the middle line, and external branches which are distributed to the integument upon the side of the lumbar and in the gluteal region.

INTERCOSTAL NERVES.—The Intercostal nerves receive one or two filaments from the adjoining ganglia of the sympathetic, and pass forwards in the intercostal space with the intercostal vessels, lying below the veins and artery, and supplying the intercostal muscles in their course. At the termination of the intercostal spaces near the sternum, the nerves pierce the intercostal and pectoral muscles, and incline downwards and outwards to be distributed to the integument of the mamma and front of the chest. Those which are situated between the false ribs pass behind the costal cartilages, and between the transversalis and obliquus internus muscles, and supply the rectus and the integument on the front of the abdomen. The first and last dorsal nerves are exceptions to this distribution. The anterior branch of the first dorsal nerve divides into two branches; a smaller, which takes its course along the under surface of the first rib to the sternal extremity of the first intercostal space; and a larger, which crosses obliquely the neck of the first rib, to join the brachial plexus. The last dorsal nerve, next in size to the first, sends a branch of communication to the first lumbar nerve, to assist in forming the lumbar plexus.

The Branches of each intercostal nerve are, a muscular twig to the intercostal and neighbouring muscles, and a cutaneous branch which is
given off at about the middle of the arch of the rib. The first intercostal nerve has no cutaneous branch. The cutaneous branches of the second and third intercostal nerves are named, from their origin and distribution, intercosto-humeral.

The **First intercosto-humeral nerve** is of large size; it pierces the external intercostal muscle of the second intercostal space, and divides into an internal and an external branch. The *internal branch* is distributed to the integument of the inner side of the arm. The *external branch* communicates with the nerve of Wrisberg, and divides into filaments which supply the integument upon the inner and posterior aspect of the arm as far as the elbow. This nerve sometimes takes the place of the nerve of Wrisberg.

The **Second intercosto-humeral nerve** is much smaller than the preceding; it emerges from the external intercostal muscle of the third intercostal space between the serrations of the serratus magnus muscle, and divides into filaments which are distributed to the integument of the shoulder. One of these filaments may be traced inwards to the integument of the mamma. The two intercosto-humeral nerves not unfrequently communicate previously to their distribution.

The cutaneous branches of the *fourth* and *fifth* intercostal nerve send anterior twigs to the integument of the mammary gland and posterior filaments to the scapular region of the back. The *cutaneous branches* of the remaining intercostal nerves reach the surface between the serrations of the serratus magnus muscle above and the external oblique below, and each nerve divides into an *anterior* and a *posterior* branch; the former being distributed to the integument of the anterolateral, and the latter to that of the lateral part of the trunk.

The cutaneous branch of the *last dorsal nerve* is remarkable for its size (n. clunium superior anticus); it pierces the internal and external oblique muscles, crosses the anterior part of the crest of the ilium, and is distributed to the integument of the gluteal region as low down as the trochanter major.

**Lumbar Nerves.**

There are five pairs of lumbar nerves, of which the first makes its appearance between the first and second lumbar vertebrae, and the last between the fifth lumbar and the base of the sacrum. The *anterior* branches increase in size from above downwards. They communicate at their origin with the lumbar ganglia of the sympathetic, and pass obliquely outwards behind the psoas magnus or between its fasciculi, sending twigs to that muscle and to the quadratus lumbarorum. In this situation each nerve divides into two branches, a superior branch which ascends to form a loop of communication with the nerve above, and an inferior branch which descends to join in like manner the nerve below, the communications and anastomoses which are thus established constituting the lumbar plexus.

The *posterior* branches diminish in size from above downwards; they
pass backwards between the transverse processes of the corresponding vertebrae, and each nerve divides into an internal and an external branch. The *internal* branch, the smaller of the two, passes inwards to be distributed to the multifidus spinae and interspinales, and becoming cutaneous supplies the integument of the lumbar region on the middle line. The *external* branches communicate with each other by several loops, and, after supplying the deeper muscles, pierce the sacro-lumbalis to reach the integument to which they are distributed. The external branches of the three lower lumbar nerves (nervi clunium superiores postici) descend over the posterior part of the crest of the ilium, and are distributed to the integument of the gluteal region.

**LUMBAR PLEXUS.**

The *Lumbar plexus* is formed by the communications and anastomoses which take place between the anterior branches of the five lumbar nerves, and between the latter and the last dorsal. It is narrow above and increases in breadth inferiorly, and is situated between the transverse processes of the lumbar vertebrae and the quadratus lumbarum behind, and the psoas magnus muscle in front.

The *Branches of the lumbar plexus* are the—

- Musculo-cutaneous,
- External-cutaneous,
- Genito-crural,
- Crural,
- Obturator,
- Lumbo-sacral.

The *Musculo-cutaneous nerves*, two in number, superior and inferior, proceed from the first lumbar nerve. The *superior musculo-cutaneous nerve* (ilio-scrotal, ilio-hypogastricus), passes outwards between the posterior fibres of the psoas magnus, and crossing obliquely the quadratus lumbarum to the middle of the crest of the ilium, pierces the transversalis muscle, and gives off a cutaneous branch. It then winds along the crest of the ilium between the transversalis and internal oblique, and divides into two branches, abdominal and scrotal. The *abdominal branch* is continued forwards parallel with the last intercostal nerve to near the rectus muscle, to which it sends branches and perforates the aponeuroses of the internal and external oblique to be distributed to the integument of the mons pubis and groin. The *scrotal branch*, opposite the anterior superior spinous process of the ilium, communicates with the inferior musculo-cutaneous nerve, and passes forward to the external abdominal ring. It then pierces the cremaster muscle and accompanies the spermatic cord in the male, and the round ligament in the female, to be distributed to the integument of the scrotum or external labium. The *inferior musculo-cutaneous nerve*
(ilio-inguinal) also arises from the first lumbar nerve. It is much smaller than the preceding, crosses the quadratus lumborum below it, and curves along the crest of the ilium to the anterior superior spinous process, resting in its course upon the iliac fascia. It there pierces the transversalis fascia and muscle, communicates with the scrotal branch of the ilio-scrotal nerve, and passes along the spermatic canal with the spermatic cord to be similarly distributed.

The **EXTERNAL CUTANEOUS NERVE** (inguino-cutaneous) proceeds from the second lumbar nerve. It pierces the posterior fibres of the psoas muscle; and crossing the iliacus obliquely, lying upon the iliac fascia, to the anterior superior spinous process of the ilium, passes into the thigh beneath Poupart's

* A diagram shewing the lumbar and sacral plexuses, with the nerves of the lower extremity. 1. The five lumbar nerves; which with a branch from the last dorsal, constitute the lumbar plexus. 2. The four upper sacral nerves; which, with the last lumbar, form the sacral plexus. 3. The two musculo-cutaneous nerves, branches of the first lumbar nerve. 4. The external cutaneous nerve. 5. The genito-crural nerve. 6. The crural or femoral nerve. 7. Its muscular branches. 8. Its cutaneous branches, middle cutaneous. 9. Its descending or saphenous branches. 10. The short saphenous nerve. 11. The long or internal saphenous. 12. The obturator nerve. 13. The gluteal nerve; a branch of the lumbo-sacral nerve. 14. The internal pudic nerve. 15. The lesser ischiatic nerve. 16. The greater ischiatic nerve. 17. The popliteal nerve. 18. The peroneal nerve. 19. The muscular branches of the popliteal. 20. The posterior tibial nerve; dividing at 21, into the two plantar nerves. 22. The external saphenous nerve, formed by the union of the communicans poplitei and communicans peronei. 23. The anterior tibial nerve. 24. The musculo-cutaneous nerve, piercing the deep fascia, and dividing into two cutaneous branches, for the supply of the dorsum of the foot.
ligament. It then pierces the fascia lata at about two inches below the anterior superior spine of the ilium, and divides into two branches, anterior and posterior. The posterior branch crosses the tensor vaginae femoris muscle to the outer and posterior side of the thigh, and supplies the integument in that region. The anterior nerve divides into two branches which are distributed to the integument upon the outer border of the thigh, and to the articulation of the knee.

The Genito-crural proceeds also from the second lumbar nerve. It traverses the psoas magnus from behind forwards, and runs down on the anterior surface of that muscle and beneath its fascia to near Poupart's ligament, where it divides into a genital and a crural branch. The genital branch (n. spermaticus seu pudendus externus) crosses the external iliac artery to the internal abdominal ring and descends along the spermatic canal, lying behind the cord to the scrotum, where it divides into branches which supply the spermatic cord and cremaster in the male, and the round ligament and external labium in the female. At the internal abdominal ring this nerve sends off a branch which after supplying the lower border of the internal oblique and transversalis, is distributed to the integument of the groin. The crural branch (lumbo-inguinalis), the most external of the two, descends along the outer border of the external iliac artery and, crossing the origin of the circumflex ilii artery, enters the sheath of the femoral vessels in front of the femoral artery. It pierces the sheath below Poupart's ligament, and is distributed to the integument of the anterior aspect of the thigh as far as its middle. This nerve is often very small, and sometimes communicates with one of the cutaneous branches of the crural nerve.

The Crural, or Femoral nerve, is the largest of the divisions of the lumbar plexus; it is formed by the union of branches from the second, third, and fourth lumbar nerves, and, emerging from beneath the psoas muscle, passes downwards in the groove between it and the iliacus, and beneath Poupart's ligament into the thigh, where it spreads out and divides into numerous branches. At Poupart's ligament it is separated from the femoral artery by the breadth of the psoas muscle, which at this point is scarcely more than half an inch in diameter, and by the iliac fascia, beneath which it lies.

Branches.—While situated within the pelvis the crural nerve gives off several muscular branches to the iliacus, and one to the psoas. On emerging from beneath Poupart's ligament the nerve becomes flattened and divides into numerous branches, which may be arranged into,—

Cutaneous,
Muscular,
Branch to the femoral sheath,
Short saphenous nerve,
Long saphenous nerve.

The Cutaneous nerves (middle cutaneous) two in number, proceed
from the anterior part of the crural, and after perforating the sartorius muscle to which they give filaments, pierce the fascia lata and are distributed to the integument of the middle and lower part of the thigh and of the knee. The most external of these nerves perforates the upper part of the sartorius, communicates with the crural branch of the genito-crural, divides into two branches at about the middle of the thigh, and gives off numerous filaments to the anterior and outer aspect of the limb as far as the patella. The internal nerve perforates the muscle at about its middle, pierces the fascia lata at the lower third of the thigh, descends to the inner condyle, and curves forward to the front of the knee, supplying the integument by many filaments. Besides these another cutaneous branch derived from the muscular branch to the vastus externus is found on the outer side of the lower third of the thigh.

The Muscular branches are several large twigs which are distributed to the muscles of the anterior aspect of the thigh. One of these is sent to the rectus; one to the vastus externus, which gives off a cutaneous twig to the outer aspect of the thigh; one to the cruraeus, and one large and long branch to the vastus internus. From the two latter, filaments are distributed to the periostium and knee-joint. The sartorius receives its supply of nerves from the cutaneous nerves by which it is perforated.

The Branch to the femoral sheath is a small nerve which passes inwards to the sheath of the femoral vessels at the upper part of the thigh, and divides into several filaments which surround the femoral and profunda vessels. Two of these filaments, one from the front, and the other from the posterior part of the sheath, unite to form a small nerve which escapes from the saphenous opening and passes downwards with the saphenous vein. Other filaments are distributed to the adductor muscles, and communicate with the long saphenous nerve.

The Short saphenous nerve (n. cutaneus internus) inclines inwards to the sheath of the femoral vessels, and divides into a superficial and a deep branch. The superficial branch passes downwards along the inner border of the sartorius muscle to the lower third of the thigh; it then pierces the fascia lata, joins the internal saphenous vein, and accompanies that vessel to the knee-joint, where it terminates by communicating with the long saphenous nerve. The deep branch descends on the outer side of the sheath of the femoral vessels, and crosses the sheath at its lower part to a point opposite the termination of the femoral artery, where it divides into several filaments which constitute a plexus by their communication with other nerves. One of these filaments communicates with the descending branch of the obturator nerve, another with the long saphenous nerve, and two or three are distributed to the integument upon the internal and posterior aspect of the thigh.

The Long saphenous nerve (n. cutaneus internus longus) inclines inwards to the sheath of the femoral vessels, and entering the sheath
accompanies the femoral artery to the aponeurotic canal formed by the adductor longus and vastus internus muscles. It then quits the artery, and, passing between the tendons of the sartorius and gracilis, descends along the inner side of the leg with the internal saphenous vein, crosses in front of the inner ankle, and is distributed to the integument on the inner side of the foot as far as the great toe.

The internal saphenous nerve receives from the obturator nerve two branches of communication, one near its upper part, which passes through the angle of division of the femoral artery, and the other at the internal condyle. The branches which it gives off in its course are, a femoral cutaneous branch, at about the middle of the thigh, distributed to the integument of the inner and posterior aspect of the limb, and communicating with other cutaneous filaments from the saphenous below the knee; a tibial cutaneous branch proceeding from the nerve a little above the internal condyle, passing between the sartorius and gracilis and descending the inner aspect of the leg to the ankle; an articular branch of small size, proceeding from the nerve, while in the aponeurotic canal of the femoral artery and passing directly to the knee-joint to supply the synovial membrane; an anterior cutaneous branch proceeding from the saphenous at the inner condyle, perforating the sartorius, and dividing into a number of filaments which supply the integument over the patella and around the joint, and the integument of the front and outer aspect of the leg as far as the ankle; lastly, cutaneous filaments below the knee to supply the inner side and front of the leg and foot, and articular branches to the ankle-joint.

The Obturator Nerve is formed by a branch from the third, and another from the fourth lumbar nerve. It passes downwards among the fibres of the psoas muscle, through the angle of bifurcation of the common iliac vessels, and along the inner border of the brim of the pelvis, to the obturator foramen, where it joins the obturator artery. Having escaped from the pelvis it gives off two small twigs to the obturator externus muscle and divides into four branches, three anterior, which pass in front of the adductor brevis, supplying that muscle, the pectineus, the adductor longus, and the gracilis; and a posterior branch which passes downwards behind the adductor brevis, and ramifies in the adductor magnus.

From the branch which supplies the adductor brevis, a communicating filament passes outwards through the angle of bifurcation of the femoral vessels to unite with the long saphenous nerve. From the branch to the adductor longus a long cutaneous nerve proceeds, which issues from beneath the inferior border of that muscle, sends filaments of communication to the plexus of the short saphenous nerve, and descends to the inner side of the knee, where it pierces the fascia and communicates with the long saphenous nerve. It is distributed to the integument upon the inner side of the leg. From the posterior branch an articular branch is given off which pierces the adductor magnus
muscle, accompanies the popliteal artery, and is distributed to the
synovial membrane of the knee-joint on its posterior aspect.

The LUMBO-SACRAL NERVE.—The anterior division of the fifth
lumbar nerve, conjoined with a branch from the fourth, constitutes the
lumbo-sacral nerve which descends over the base of the sacrum into
the pelvis, and assists in forming the sacral plexus.

SACRAL NERVES.

There are six pairs of sacral nerves; the first escape from the ver-
tebral canal through the first sacral foramina, and the two last between
the sacrum and coccyx. The posterior sacral nerves are very small
and diminish in size from above downwards; they communicate with
each other immediately after their escape from the posterior sacral
foramina, and divide into external and internal branches. The
external branches pierce the gluteus maximus, to which they give fila-
ments, and are distributed to the integument of the posterior part of
the gluteal region (n. cutanei clunium posteriores). The internal
supply the integument over the sacrum and coccyx.

The anterior sacral nerves diminish in size from above downwards;
the first is large and unites with the lumbo-sacral nerve; the second,
of equal size, unites with the preceding; the third, which is scarcely
one-fourth so large as the third, also joins with the preceding nerves in
the formation of the sacral plexus. The fourth anterior sacral nerve is
about one-third the size of the preceding sacral nerve, it divides into
several branches, one of which is sent to the sacral plexus, a second to
join the fifth sacral nerve, a third to the viscera of the pelvis commu-
nicating with the hypogastric plexus, and a fourth to the coccygeus
muscle, and to the integument around the anus. The fifth anterior
sacral nerve presents about half the size of the fourth; it divides into
two branches, one of which communicates with the fourth, the other
with the sixth. The sixth sacral nerve (coccygeal) is exceedingly
small; it gives off an ascending filament which is continuous with the
communicating branch of the fifth; and a descending filament which
passes downwards by the side of the coccyx and traverses the fibres
of the great sacro-ischiatric ligament to be distributed to the gluteus
maximus and to the integument. All the anterior sacral nerves re-
cieve branches from the sacral ganglia of the sympathetic at their
emergence from the sacral foramina.

SACRAL PLEXUS.

The Sacral plexus is formed by the lumbo-sacral, and by the ante-
rior branches of the four upper sacral nerves. The plexus is trian-
gular in form, the base corresponding with the whole length of the
sacrum, and the apex with the lower part of the great ischiatic fora-
men. It is in relation behind with the pyriformis muscle, and in front with the pelvic fascia, which latter separates it from the branches of the internal iliac artery, and from the viscera of the pelvis.

The Branches of the sacral plexus are divisible into the internal and the external; they may be thus arranged:

**Internal.**
- Visceral,
- Muscular.

**External.**
- Muscular,
- Gluteal,
- Internal pudic,
- Lesser ischiatic,
- Greater ischiatic.

The Visceral nerves are three or four large branches which are derived from the fourth and fifth sacral nerves: they ascend upon the side of the rectum and bladder; in the female upon the side of the rectum, the vagina and the bladder; and interlace with the branches of the hypogastric plexus, sending in their course numerous filaments to those viscera.

The Muscular branches given off within the pelvis are one or two twigs to the levator ani; an obturator branch; which curves around the spine of the ischium to reach the internal surface of the obturator internus muscle; a coccygeal branch; and an haemorrhoidal nerve which passes through the two ischiatic openings and descends to the termination of the rectum to supply the sphincter and the integument.

The Muscular branches supplied by the sacral plexus externally to the pelvis are, a branch to the pyramidalis; a branch to the gemellus superior; and a branch of moderate size which descends between the gemelli muscles and the ischium, and is distributed to the gemellus inferior, the quadratus femoris, and the capsule of the hip-joint.

The Gluteal Nerve (superior gluteal) is a branch of the lumbo-sacral; it passes out of the pelvis with the gluteal artery, through the great sacro-ischiatic foramen, and divides into a superior and an inferior branch. The superior branch follows the direction of the superior curved line of the ilium, accompanying the deep superior branch of the gluteal artery, and sending filaments to the gluteus medius and minimus. The inferior passes obliquely downwards and forwards between the gluteus medius and minimus, distributing numerous filaments to both, and terminates in the tensor vaginae femoris muscle.

The Internal Pudic Nerve arises from the lower part of the sacral plexus, passes out of the pelvis through the great sacro-ischiatic foramen below the pyriformis muscle, and takes the course of the internal pudic artery. While situated beneath the obturator fascia it lies below that vessel and divides into a superior and an inferior branch.
The Superior nerve (dorsalis penis) ascends upon the posterior surface of the ramus of the ischium, pierces the deep perineal fascia and accompanies the artery dorsalis penis to the glans, to which it is distributed. At the root of the penis this nerve gives off a cutaneous branch which runs along the side of the organ, gives filaments to the corpus cavernosum, and with its fellow of the opposite side supplies the integument of the upper two-thirds of the penis and prepuce.

The Inferior or perineal nerve pursues the course of the internal pudic artery in the perineum and sends off three principal branches, an external perineal branch, which ascends upon the outer side of the crus penis, and supplies the scrotum; a superficial perineal branch, which accompanies the artery of that name and distributes filaments to the scrotum, to the integument of the under part of the penis and to the prepuce; and, thirdly, the bulbou-urethral branch, which sends twigs to the sphincter ani, transversus perinei, and accelerator urinæ, and terminates by ramifying in the corpus spongiosum.

In the female the internal pudic nerve is distributed to the parts analogous to those of the male. The superior branch supplies the clitoris; and the inferior the vulva and parts in the perineum.

The Lesser ischiatic nerve passes out of the pelvis through the great sacro-ischiatric foramen below the pyriformis muscle, and divides into muscular and cutaneous branches. The muscular branches, inferior gluteal, are distributed to the gluteus maximus; some ascending in the substance of that muscle to its upper border, and others descending. The cutaneous branches are, several ascending filaments to the integument over the gluteus maximus (n. cutanei clunium inferiores), perineal cutaneous, and middle posterior cutaneous.

The Perineal cutaneous nerve (pudendalis longus inferior), curves around the tuberosity of the ischium and ascends in a direction parallel to the ramus of the ischium and os pubis to the scrotum, where it communicates with the superficial perineal nerve, and divides into an internal and an external branch. The internal branch passes down upon the inner side of the testis to the scrotum; the external branch to its outer side, and both terminate in the integument of the under border of the penis.

The Middle posterior cutaneous nerve crosses the tuberosity of the ischium and pierces the deep fascia at the lower border of the gluteus maximus. It then passes downwards along the middle of the posterior aspect of the thigh and of the popliteal region, and is distributed to the integument as far as the middle of the calf of the leg. In its course the nerve gives off several cutaneous branches to the integument of the inner and outer side of the thigh, and in the popliteal region a communicating branch which pierces the fascia of the leg and unites with the external saphenous nerve.

The Great ischiatic nerve is the largest nervous cord in the body; it is formed by the sacral plexus, or rather is a prolongation of
the plexus, and at its exit from the great sacro-ischiatic foramen beneath the pyriformis muscle measures three quarters of an inch in breadth. It descends through the middle of the space between the trochanter major and tuberosity of the ischium, and along the posterior part of the thigh to about its lower third, where it divides into two large terminal branches, popliteal and peroneal. This division sometimes takes place at the plexus, and the two nerves descend together side by side; occasionally they are separated at their commencement by a part or the whole of the pyriformis muscle. The nerve in its course down the thigh rests upon the gemellus superior, tendon of the obturator internus, gemellus inferior, quadratus femoris, and adductor magnus muscle, and is covered in by the gluteus maximus, biceps, semitendinosus, and semimembranosus.

The Branches of the great ischiatic nerve, previously to its division, are muscular and articular. The muscular branches are given off from the upper part of the nerve and supply both heads of the biceps, the semi-tendinosus, semi-membranosus, and adductor magnus. The articular branch descends to the upper part of the external condyle of the femur, and divides into filaments which are distributed to the fibrous capsule and to the synovial membrane of the knee-joint.

The Popliteal nerve passes through the middle of the popliteal space, from the division of the great ischiatic nerve to the lower border of the popliteus muscle, accompanies the artery beneath the arch of the soleus, and becomes the posterior tibial nerve. It is superficial in the whole of its course, and lies externally to the vein and artery.

The Branches of the popliteal nerve are muscular or sural, and articular, and a cutaneous branch the communicans poplitei.

The Muscular branches, of considerable size, and four or five in number, are distributed to the two heads of the gastrocnemius, to the soleus, plantaris, and popliteus.

The Articular nerve pierces the ligamentum posticum Winslowii, and supplies the interior of the knee-joint. It usually sends a twig to the popliteus muscle.

The Communicans poplitei (communicans tibialis) is a large nerve which arises from the popliteal at about the middle of its course, and descends between the two heads of the gastrocnemius, and along the groove formed by the two bellies of that muscle; at a variable distance below the articulation of the knee it receives a large branch, the communicans peronei, from the peroneal nerve, and the two together constitute the external saphenous nerve.

The External saphenous nerve pierces the deep fascia below the fleshy part of the gastrocnemius muscle, and continues its course down the leg, lying along the outer border of the tendo Achillis and by the side of the external saphenous vein which it accompanies to the foot. At the lower part of the leg it winds around the outer malleolus, and is distributed to the outer side of the foot and little toe, communicating with the external peroneal cutaneous nerve,
and sending numerous filaments to the integument of the heel and sole of the foot.

The Posterior Tibial Nerve is continued along the posterior aspect of the leg from the lower border of the popliteus muscle to the posterior part of the inner ankle, where it divides into the internal and external plantar nerve. In the upper part of its course it lies to the outer side of the posterior tibial artery; it then becomes placed superficially to that vessel, and at the ankle is again situated to its outer side; in the lower third of the leg it lies parallel with the inner border of the tendo Achillis.

The Branches of the posterior tibial nerve are three or four muscular twigs to the deep muscles of the posterior aspect of the leg, the branch to the flexor longus pollicis accompanies the fibular artery; one or two filaments which entwine around the artery and then terminate in the integument; and two or three plantar cutaneous branches which pass downwards upon the inner side of the os calcis and are distributed to the integument of the heel.

The Internal Plantar Nerve, larger than the external, crosses the posterior tibial vessels to enter the sole of the foot, where it lies in the interspace between the abductor pollicis and flexor brevis digitorum; it then enters the sheath of the latter muscle, and divides opposite the bases of the metatarsal bones into three digital branches; one to supply the adjoining sides of the great and second toe; the second the adjoining sides of the second and third toe; and the third the corresponding sides of the third and fourth toes. This distribution is precisely similar to that of the digital branches of the median nerve.

In its course the internal plantar nerve gives off cutaneous branches to the integument of the inner side and sole of the foot; muscular branches to the muscles forming the inner and middle group of the sole; a digital branch to the inner border of the great toe; and articular branches to the articulations of the tarsal and metatarsal bones.

The External Plantar Nerve, the smaller of the two, follows the course of the external plantar artery to the outer border of the musculus accessorius, beneath which it sends several large muscular branches to supply the adductor pollicis and the articulations of the tarsal and metatarsal bones. It then gives branches to the integument of the outer border and sole of the foot, and sends forward two digital branches to supply the little toe and one half the next.

* It is extremely interesting in a physiological point of view, to observe the mode of distribution of these filaments. I have traced them in relation with several, and I have no doubt that they exist in connection with all the superficial arteries. They seem to be the direct monitors to the artery of the presence or approach of danger.
The *Peroneal Nerve* is is one half smaller than the popliteal; it passes downwards by the side of the tendon of the biceps, crossing the inner head of the gastrocnemius and the origin of the soleus, to the neck of the fibula, where it pierces the origin of the peroneus longus muscle, and divides into two branches, the anterior tibial and musculo-cutaneous.

The *Branches* of the peroneal nerve previously to its division are, the communicans peronei, cutaneous, articular and muscular. The *communicans peronei*, much smaller than the communicans poplitei, crosses the external head of the gastrocnemius to the middle of the leg. It there sends a large branch to join the communicans poplitei and constitute the external saphenous nerve, and descends very much reduced in size with the external saphenous vein to the side of the external ankle, to which and to the integument of the heel it distributes filaments. The *cutaneous* branch passes down the outer side of the leg, supplying the integument. The *articular* is a small branch distributed to the knee-joint. The *muscular* branches are twigs to the short head of the biceps, peroneus longus and tibialis anticus.

The *Anterior Tibial Nerve* commences at the bifurcation of the peroneal, upon the head of the fibula, and passes beneath the upper part of the extensor longus digitorum, to reach the outer side of the anterior tibial artery, just as that vessel has emerged through the opening in the interosseous membrane. It descends the anterior aspect of the leg with the artery; lying at first to its outer side, and then in front of it, and near the ankle becomes again placed to its outer side. Reaching the ankle it passes beneath the annular ligament; accompanies the dorsalis pedis artery, supplies the adjoining sides of the great and second toes, and communicates with the internal peroneal cutaneous nerve.

The *Branches* given off by the anterior tibial nerve are, *muscular* to the muscles in its course, and on the foot a *tarsal* branch which passes beneath the extensor brevis digitorum, and distributes filaments to the interossei muscles and to the articulations of the tarsus and metatarsus.

The *Musculo-cutaneous* nerve passes downwards in the direction of the fibula, in the substance of the peroneus longus; it then passes forwards to get between the peroneus longus and brevis, and at the lower third of the leg pierces the deep fascia, and divides into two peroneal cutaneous branches. In its course it gives off several branches to the peronei muscles.

The *Peroneal cutaneous* nerves pass in front of the ankle-joint, and are distributed to the integument of the foot and toes; the external supplying three toes and a half, and the internal one and a half. They communicate with the saphenous and anterior tibial nerves. The external saphenous nerve frequently supplies the fifth toe and the adjoining side of the fourth.
SYMPATHETIC NERVES.

The Sympathetic system consists of a series of ganglia, extending along each side of the vertebral column from the head to the coccyx, communicating with all the other nerves of the body, and distributing branches to all the internal organs and viscera.

It communicates with the other nerves immediately at their exit from the cranium and vertebral canal. The fourth and sixth nerves, however, form an exception to this rule; for with these it unites in the cavernous sinus; and with the olfactory, optic, and auditory, at their ultimate expansions.

The branches of distribution accompany the arteries which supply the different organs, and form communications around them, which are called plexuses, and take the name of the artery with which they are associated: thus we have the mesenteric plexus, hepatic plexus, splenic plexus, &c. All the internal organs of the head, neck, and trunk are supplied with branches from the sympathetic, and some of them exclusively; hence it is considered a nerve of organic life.

It is called the ganglionic nerve from the circumstance of being formed by a number of ganglia; and from the constant disposition which it evinces in its distribution, to communicate and form small knots or ganglia.

There are five sympathetic ganglia in the head; viz., the ganglion of Ribes; the ciliary or lenticular; the sphenopalatine, or Meckel's; the otic, or Arnold's; and the submaxillary: three in the neck; superior, middle, and inferior: twelve in the dorsal region; four in the lumbar region; and four or five in the sacral region.

Each ganglion may be considered as a distinct centre giving off branches in four different directions, viz., superior or ascending to communicate with the ganglion above; inferior or descending, to communicate with the ganglion below; external to communicate with the spinal nerves; and internal, to communicate with the sympathetic filaments of the opposite side, and to be distributed to the viscera.

CRANIAL GANGLIA.

Ganglion of Ribes,
Ciliary, or lenticular ganglion,
Sphenopalatine, or Meckel's ganglion,
Otic, or Arnold's ganglion,
Submaxillary ganglion.

The Ganglion of Ribes is a small ganglion situated upon the anterior communicating artery, and formed by the union of the sympathetic filaments, which accompany the ramifications of the two anterior cerebral arteries. These filaments are derived from the carotid plexus, at each side; and through their intervention, the ganglion of Ribes is
brought into connection with the carotid plexus, and with the other ganglia of the sympathetic. This ganglion, though of very small size, is interesting, as being the superior point of union between the sympathetic chains of opposite sides of the body.

The Ciliary ganglion (lenticular) is a small quadrangular and

\[\text{Fig. 151.}\]

* The cranial ganglia of the sympathetic nerve.  1. The ganglion of Ribes.  2. The filament by which it communicates with the carotid plexus (3).  4. The ciliary or lenticular ganglion, giving off ciliary branches for the supply of the globe of the eye.  5. Part of the inferior division of the third nerve, receiving a short thick branch (the short root) from the ganglion.  6. Part of the nasal nerve, receiving a longer branch (the long root) from the ganglion.  7. A slender filament (the sympathetic root) sent directly backwards from the ganglion to the carotid plexus.  8. Part of the sixth nerve in the cavernous sinus, receiving two branches from the carotid plexus.  9. Meckel's ganglion (spheno-palatine).  10. Its ascending branches, communicating with the superior maxillary nerve.  11. Its descending or palatine branches.  12. Its internal branches, spheno-palatine or nasal.  13. The naso-palatine branch, one of the nasal branches.  * The naso-palatine ganglion.  14. The posterior branch of the ganglion, the Vidian nerve.  15. Its carotid branch (n. petrosus profundus) communicating with the carotid plexus.  16. Its petrosal branch (n. petrosus superficialis minor), joining the intumescentia gangliformis of the facial nerve.  17. The facial nerve.  18. The chorda tympani nerve, which descends to join the gustatory nerve.  19. The gustatory nerve.  20. The submaxillary ganglion, receiving the chorda tympani, and other filaments from the gustatory.  21. The superior cervical ganglion of the sympathetic.
flattened ganglion situated within the orbit, between the optic nerve and the external rectus muscle; it is in close contact with the optic nerve, and is surrounded by adipose tissue, which renders its dissection somewhat difficult.

Its branches of distribution are the ciliary, which arise from its anterior angles by two groups: the upper group, consisting of about four filaments; and the lower, of five or six. They accompany the ciliary arteries in a waving course, and divide into a number of filaments which pierce the sclerotic around the optic nerve, and supply the tunic of the eye-ball. A small filament is said by Tiedemann, to accompany the arteria centralis retinae into the centre of the globe of the eye.

Its branches of communication are three, one, the long root, which proceeds from the posterior superior angle to the nasal branch of the ophthalmic nerve; a short thick branch, the short root, from the posterior inferior angle to the inferior division of the third nerve; and a slender filament, the sympathetic root, which passes backwards to the cavernous sinus, and communicates with the carotid plexus. Occasionally the ciliary ganglion receives also a filament of communication (middle root) from the sphenopalatine ganglion; and it sometimes sends a twig to the abducens nerve.

The Sphenopalatine ganglion (Meckel's) the largest of the cranial ganglia of the sympathetic, is very variable in its dimensions. It is situated in the sphenomaxillary fossa.

Its branches are divisible into four groups: ascending, descending, internal, and posterior.

The branches of distribution are the internal and the descending. The internal branches are the nasal and the naso-palatine. The nasal or sphenopalatine nerves, four or five in number, enter the nasal fossa through the sphenopalatine foramen, and are distributed to the mucous membrane of the superior meatus, and superior and middle spongy bones. Besides these, several branches issue through small openings in the palate and sphenoid bone and supply the mucous membrane of the upper part of the pharynx and the Eustachian tube.

The naso-palatine nerve (Scarpa) enters the nasal fossa with the nasal nerves, and crosses the roof of the nares to reach the septum, to which it gives several filaments. It then curves downwards and forwards to the naso-palatine canal, and enters the anterior palatine canal, where it joins with its fellow of the opposite side and receives filaments from the anterior dental and palatine nerves. By this junction an enlargement is formed, the naso-palatine ganglion (Cloquet's), which distributes filaments to the mucous membrane of the palate, immediately behind the incisor teeth.

The descending branches are the three palatine nerves, anterior, middle, and posterior.

The anterior palatine nerve, the largest of the three, descends from the ganglion through the posterior palatine canal, and emerges at the
posterior palatine foramen. It then passes forwards in the substance of the hard palate to which it is distributed, and communicates with the naso-palatine ganglion and with its branches. While in the posterior palatine canal this nerve gives off several branches which enter the nose through openings in the palate bone, and are distributed to the middle and inferior meatus, the inferior spongy bone, and the antrum.

The middle palatine nerve descends through the same canal to the posterior palatine foramen, and distributes branches to the tonsil, soft palate, and uvula.

The posterior palatine nerve, the smallest of the three, quits the other nerves to enter a distinct canal, from which it emerges by a separate opening behind the posterior palatine foramen. It is distributed to the hard palate and gums near the point of its emergence, and to the tonsil and soft palate.

The branches of communication are the ascending and the posterior. The ascending branches are, one or two to join the superior maxillary nerve; one to the abducent nerve; one to the ciliary ganglion constituting its middle root; and occasionally two filaments to the optic nerve within the orbit. The posterior branch is the Vidian or pterygoid nerve.

The Vidian * nerve passes directly backwards from the spheno-palatine ganglion, through the pterygoid or Vidian canal, to the foramen lacerum basis cranii, where it divides into two branches, the carotid and petrosal. The carotid branch (n. petrosus profundus) crosses the foramen lacerum, surrounded by the ligamentous substance which closes that opening and enters the carotid canal by several filaments to join the carotid plexus. The petrosal branch (n. petrosus superficialis major) enters the cranium through the foramen lacerum basis cranii, piercing the ligamentous substance of the latter, and passes backwards beneath the Casserian ganglion and dura mater, embedded in a groove upon the anterior surface of the petrous bone, to the hiatus Fallopii. In the hiatus Fallopii the petrosal branch of the Vidian receives a twig from Jacobson's nerve and terminates in the intumescentia gangliformis of the facial nerve.

While in the pterygoid canal the Vidian nerve sends off a minute branch which passes through an opening in the sphenoid bone and joins the otic ganglion.

The Otic ganglion (Arnold's) † is a small oval-shaped and flattened ganglion, resting against the inner surface of the inferior maxillary nerve, immediately below the foramen ovale; it is in relation externally with the trunk of the inferior maxillary nerve, just at

* Guido Guidi, latinised into Vidus Vidius, was professor of anatomy and medicine in the College of France in 1542. His work is posthumous, and was published in 1611.
† Frederick Arnold, "Dissertatio Inauguralis de Parte Cephalica Nervi Sympatheticil. Heidelberg, 1820; and "Ueber den Ohrknoten," 1828.
the point of union of the motor root; internally it rests against the cartilage of the Eustachian tube and tensor palati muscle; and posteriorly it is in contact with the arteria meningea media. It is closely adherent to the internal pterygoid nerve, and appears like a swelling upon that branch.

The branches of the otic ganglion are seven in number; two of distribution, and five of communication.

The branches of distribution are, a small filament to the tensor tympani muscle, and one to the tensor palati muscle; the latter is usually derived from the internal pterygoid nerve, at the point where that nerve is enclosed by the ganglion.

The branches of communication are, two or three filaments to the outer portion of the inferior maxillary nerve; one or two filaments to the auricular nerve; a filament to the chorda tympani; filaments to the arteria meningea media to communicate with the nervi molles; a filament which enters the cranium through the foramen spinosum with the arteria meningea media and accompanies the nervus petrosus superficialis minor to the hiatus Fallopii, where it joins the intumescentia gangliiformis of the facial nerve; a filament which enters the cranium through a small canal behind the foramen rotundum to join the Casserian ganglion; a filament which enters a small canal near the foramen ovale to communicate with the Vidian nerve; and the nervus petrosus superficialis minor. The latter nerve ascends from the ganglion to a small canal situated between the foramen ovale and foramen spinosum, and passes backwards on the petrous bone to the hiatus Fallopii, where it divides into two filaments. One of these filaments enters the hiatus and joins the intumescentia gangliiformis of the facial; the other passes to a minute foramen nearer the base of the petrous bone and enters the tympanum, where it communicates with a branch of Jacobson’s nerve.

The submaxillary ganglion is a small round or triangular ganglion, situated upon the submaxillary gland, in close relation with the gustatory nerve and near the posterior border of the mylo-hyoid muscle.

Its branches of distribution, six or eight in number, divide into many filaments, which supply the substance of the submaxillary gland and Wharton’s duct.

Its branches of communication are, two or three from and to the gustatory nerve; one from the chorda tympani; and one or two filaments which pass to the facial artery and communicate with the nervi molles from the cervical portion of the sympathetic.

Carotid Plexus.—The ascending branch of the superior cervical ganglion enters the carotid canal with the internal carotid artery, and divides into two branches, which form several loops of communication with each other around the artery. These branches, together with those derived from the petrosal branch of the Vidian, constitute the
carotid plexus. They also form frequently a small gangliform swelling upon the under part of the artery, which is called the carotid ganglion. The latter, however, is not constant. The continuation of the carotid plexus onwards with the artery by the side of the sella turcica, is called the cavernous plexus.

The carotid plexus is the centre of communication between all the cranial ganglia; and being derived from the superior cervical ganglion, between the cranial ganglia and those of the trunk, it also communicates with the greater part of the cerebral nerves, and distributes filaments with each of the branches of the internal carotid, which accompany those branches in all their ramifications.

Thus, the Ganglion of Ribes is formed by the union of the filaments which accompany the anterior cerebral arteries, and which meet on the anterior communicating artery. The ciliary ganglion communicates with the plexus by means of the long branch which is sent back to join it in the cavernous sinus. The spheno-palatine, and with it the naso-palatine ganglion, joins the plexus by means of the carotid branch of the Vidian. The submaxillary ganglion is brought into connection with it by means of the otic ganglion, and the otic ganglion by means of the tympanic nerve and the Vidian.

It communicates with the third nerve in the cavernous sinus, and through the ciliary ganglion; frequently with the fourth in the formation of the nerve of the tentorium; with the Casserian ganglion; with the ophthalmic division of the fifth in the cavernous sinus, and by means of the ciliary ganglion; with the superior maxillary, through the spheno-palatine ganglion; and with the inferior maxillary, through the otic ganglion. It sends two branches directly to the sixth nerve, which unite with it as it crosses the cavernous sinus; it communicates with the facial and auditory nerves, through the medium of the petrosal branch of the Vidian; and with the glosso-pharyngeal by means of two filaments to the tympanic nerve.

CERVICAL GANGLIA.

The Superior cervical ganglion is long and fusiform, of a greyish colour, smooth, and of considerable thickness, extending from within an inch of the carotid foramen in the petrous bone to opposite the lower border of the third cervical vertebra. It is in relation in front with the sheath of the internal carotid artery and internal jugular vein; and behind with the rectus anticus major muscle.

Its branches, like those of all the sympathetic ganglia in the trunk, are divisible into superior, inferior, external, and internal; to which may be added, as proper to this ganglion, anterior.

The superior (carotid nerve) is a single branch which ascends by

* Panizza, in his "Experimental Researches on the Nerves," denies this communication, and states very vaguely that "they are merely lost and entwined around it."—Edinburgh Medical and Surgical Journal, January 1836.
the side of the internal carotid, and divides into two branches; one lying to the outer side, the other to the inner side of that vessel. The two branches enter the carotid canal, and by their communications with each other and with the petrosal branch of the Vidian, constitute the carotid plexus.

The inferior or descending branch, sometimes two, is the cord of communication with the middle cervical ganglion.

The external branches are numerous, and may be divided into two sets: those which communicate with the glosso-pharyngeal, pneumogastric, and hypoglossal nerves; and those which communicate with the three first cervical nerves.

The internal branches are three in number: pharyngeal, to assist in forming the pharyngeal plexus; laryngeal, to join the superior laryngeal nerve and its branches; and the superior cardiac nerve, or nervus superficialis cordis.

The anterior branches accompany the carotid artery with its branches, around which they form intricate plexuses, and here and there small ganglia; they are called, from the softness of their texture, nervi molles, and from their reddish hue, nervi superflu.

The Middle cervical ganglion (thyroid ganglion) is of small size, and sometimes altogether wanting. It is situated opposite the fifth cervical vertebra, and rests upon the inferior thyroid artery. This relation is so constant, as to have induced Haller to name it the "thyroid ganglion."

Its superior branch, or branches, ascend to communicate with the superior cervical ganglion.

Its inferior branches descend to join the inferior cervical ganglion; one of these frequently passes in front of the subclavian artery, the other behind it.

Its external branches communicate with the third, fourth, and fifth cervical nerves.

Its internal branches are, filaments which accompany the inferior thyroid artery, the inferior thyroid plexus; and the middle cardiac nerve, nervus cardiacus magnus.

The Inferior cervical ganglion (vertebral ganglion) is much larger than the preceding, and is constant in its existence. It is of a semi-lunar form, and is situated upon the base of the transverse process of the seventh cervical vertebra, immediately behind the vertebral artery: hence its title to the designation "vertebral ganglion."

Its superior branches communicate with the middle cervical ganglion.

The inferior branches pass some before and some behind the subclavian artery, to join the first thoracic ganglion.

The external branches consist of two sets; one which communicates with the sixth, seventh, and eighth cervical and first dorsal nerve; and one which accompanies the vertebral artery along the vertebral
cardinal canal, forming the vertebral plexus. This plexus sends filaments to all
the branches given off by the artery, and communicates in the cranium
with the filaments of the carotid plexus accompanying the branches of
the internal carotid artery.

The internal branch is the inferior cardiac nerve, nervus cardiacus
minor.

Cardiac nerves.*—The superior cardiac nerve (nervus superficialis cordis) arises from the lower part of the superior cervical
ganglion; it then descends the neck behind the common carotid artery
and parallel with the trachea, crosses the inferior thyroid artery, and
running by the side of the recurrent laryngeal nerve for a short dis-
tance, passes behind the arteria innominata to the concavity of the
arch of the aorta, where it joins the cardiac ganglion.

In its course it receives branches from the pneumogastric nerve, and
sends filaments to the thyroid gland and trachea.

The Middle cardiac nerve (nervus cardiacus magnus) proceeds
from the middle cardiac ganglion, or, in its absence, from the cord of
communication between the superior and inferior. It is the largest
of the three nerves, and lies nearly parallel with the recurrent laryn-
geal. At the root of the neck it divides into several branches, which
pass some before and some behind the subclavian artery; it com-
municates with the superior and inferior cardiac, and with the pneu-
moaortic and recurrent nerves, and descends to the bifurcation of the
trachea, to the great cardiac plexus.

The Inferior cardiac nerve (nervus cardiacus minor) arises from
the inferior cervical ganglion, communicates freely with the recurrent
laryngeal and middle cardiac nerves, and descends to the front of the
bifurcation the trachea, to join the great cardiac plexus.

The Cardiac ganglion is a ganglionic enlargement of variable size,
situated beneath the arch of the aorta, to the right side of the liga-
ment of the ductus arteriosus. It receives the superior cardiac nerves
of opposite sides of the neck and a branch from the pneumogastric,
and gives off numerous branches to the cardiac plexuses.

The Great cardiac plexus is situated upon the bifurcation of the
trachea, above the right pulmonary artery, and behind the arch of the
aorta. It is formed by the convergence of the middle and inferior
cardiac nerves, and by branches from the pneumogastric and descen-
dens noni nerve, and first thoracic ganglion.

The Anterior cardiac plexus is situated in front of the ascending
aorta, near its origin. It is formed by the communications of filaments
that proceed from three different sources, namely, from the superior
cardiac nerves, crossing the arch of the aorta; from the cardiac ganglion
beneath the arch; and from the great cardiac plexus, passing between
the ascending aorta and the right auricle. The anterior cardiac plexus

* There is no constancy with regard to the origin and course of these nerves;
therefore the student must not be disappointed in finding the description in
discord with his dissection.
supplies the anterior aspect of the heart, distributing numerous filaments with the left coronary artery, which form the anterior coronary plexus.

The Posterior cardiac plexus is formed by numerous branches from the great cardiac plexus, and is situated upon the posterior part of the ascending aorta, near its origin. It divides into two sets of branches: one set accompanying the right coronary artery in the auriculo-ventricular sulcus; the other set joining the artery on the posterior aspect of the heart. They both together constitute the posterior coronary plexus.

The great cardiac plexus likewise gives branches to the auricles of the heart, and others to assist in forming the anterior and posterior pulmonary plexuses.

THORACIC GANGLIA.

The Thoracic ganglia are twelve in number on each side. They are flattened and triangular, or irregular in form, and present the peculiar grey colour and pearly lustre of the other sympathetic ganglia; they rest upon the heads of the ribs, and are covered in by the pleura costalis. The two first ganglia and the last are usually the largest.

Their branches are superior, inferior, external, and internal.

The superior and inferior are prolongations of the substance of the ganglia rather than branches; the former to communicate with the ganglion above, the latter with that below.

The external branches, two or three in number, communicate with both roots of each of the spinal nerves.

The internal branches of the five upper ganglia are pulmonary to join the pulmonary plexuses; esophageal to the esophageal plexus and aortic to the thoracic aorta and its branches; the first thoracic ganglion moreover sends branches to the cardiac plexuses. The branches of the lower ganglia are aortic, and several large cords which unite to form the two splanchnic nerves.

The Great splanchnic nerve arises from the sixth dorsal ganglion, and receives branches from the seventh, eighth, ninth, and tenth, which augment it to a nerve of considerable size. It descends in front of the vertebral column, within the posterior mediastinum, pierces the diaphragm immediately to the outer side of each crus, and terminates in the semilunar ganglion.

The Lesser splanchnic nerve (renal) is formed by filaments from the tenth, eleventh, and sometimes from the twelfth dorsal ganglion. It pierces the diaphragm, and descends to join the renal plexus.

The Semilunar ganglion is a large, irregular, gangliform body, pierced by numerous openings, and appearing like the aggregation of a number of smaller ganglia, having spaces between them. It is situated by the side of the celiac axis, and communicates with the ganglion of the opposite side, both above and below that trunk, so as
LUMBAR GANGLIA.

489

to form a gangliform circle, from which branches pass off in all directions, like rays from a centre. Hence the entire circle has been named the solar plexus.

The Solar plexus receives the great splanchnic nerves; part of the lesser splanchnic nerves; the termination of the right pneumogastric nerve; some branches from the right phrenic nerve; and sometimes one or two filaments from the left. It sends numerous filaments which accompany, under the name of plexuses, all the branches given off by the abdominal aorta. Thus, we have derived from the solar plexus the—

Phrenic plexuses,
Gastric plexus,
Hepatic plexus,
Splanic plexus,
Supra-renal plexuses,
Renal plexuses,
Superior mesenteric plexus,
Spermatic plexuses,
Inferior mesenteric plexus.

The Renal plexus is formed chiefly by the lesser splanchnic nerve, but receives many filaments from the solar plexus.

The Spermatic plexus is formed principally by the renal plexus.

The Inferior mesenteric plexus receives filaments from the aortic plexus.

LUMBAR GANGLIA.

The Lumbar ganglia are four in number on each side, of the peculiar pearly grey colour, fusiform, and situated upon the anterior part of the bodies of the lumbar vertebrae.

The superior and inferior branches of the lumbar ganglia are branches of communication with the ganglion above and below, as in the dorsal region.

The external branches, two or three in number, communicate with the lumbar nerves.

The internal branches consist of two sets; of which the upper pass inwards in front of the abdominal aorta, and form around that trunk a plexiform interlacement, which constitutes the lumbar aortic plexus; the lower branches cross the common iliac arteries, and unite over the promontory of the sacrum, to form the hypogastric plexus.

The Lumbar aortic plexus is formed by branches from the lumbar ganglia, and receives filaments from the solar and superior mesenteric plexuses. It sends filaments to the inferior mesenteric plexus, and terminates in the hypogastric plexus.

The Hypogastric plexus is formed by the termination of the aortic plexus, and by the union of branches from the lower lumbar ganglia. It is situated over the promontory of the sacrum, between the two
SACRAL GANGLIA.

The Sacral ganglia are four or five in number on each side. They are situated upon the sacrum, close to the anterior sacral foramina, and resemble the lumbar ganglia in form and mode of connection, although much smaller in size.

The superior and inferior branches communicate with the ganglia above and below.

The external branches communicate with the sacral nerves.

The internal branches communicate very freely with the lateral divisions of the hypogastric plexus, and are distributed to the pelvic viscera. The last pair of sacral ganglia give off branches which join a small ganglion, situated on the first bone of the coccyx, called the ganglion impar, or azygos. This ganglion resembles in its position and function the ganglion of Ribes, serving to connect the inferior extremity of the sympathetic system, as does the former ganglion its upper extremity: It gives off a few small branches to the coccyx and rectum.
CHAPTER IX.

ORGANS OF SENSE.

The organs of sense, the instruments by which the animal frame is brought into relation with surrounding nature, are five in number. Four of these organs are situated within the head, viz. the apparatus of smell, sight, hearing, and taste, and the remaining organ, of touch, is resident in the skin, and distributed over the surface of the body.

THE NOSE AND NASAL FOSSE.

The organ of smell consists essentially of two parts: one external, the nose; the other internal, the nasal fossae.

The nose is the triangular pyramid projecting from the centre of the face, immediately above the upper lip. Superiorly, it is connected with the forehead, by means of a narrow bridge; inferiorly, it presents two openings, the nostrils, which overhang the mouth, and are so constructed that the odour of all substances must be received by the nose before they can be introduced within the lips. The septum between the openings of the nostrils is called the columna. Their entrance is guarded by a number of stiff hairs (vibrissae) which project across the openings, and act as a filter in preventing the introduction of foreign substances, such as dust or insects, with the current of air intended for respiration.

The anatomical elements of which the nose is composed are,—1, Integument. 2. Muscles. 3. Bones. 4. Fibro-cartilages. 5. Mucous membrane. 6. Vessels and nerves.

1. The Integument forming the tip (lobulus) and wings (ala) of the nose is extremely thick and dense, so as to be with difficulty separated from the fibro-cartilage. It is furnished with an abundance of sebaceous follicles, which by their oily secretion, protect the extremity of the nose in excessive alternations of temperature. The sebaceous matter of these follicles becomes of a dark colour upon the surface, from the attraction of the carbonaceous matter floating in the atmosphere; hence the spotted appearance which the tip of the nose presents in large cities. When the integument is firmly compressed, the inspissated sebaceous secretion is squeezed out from the follicles, and, taking the cylindrical form of their excretory ducts, has the appearance of small white maggots with black heads.
2. The *Muscles* are brought into view by reflecting the integument: they are the pyramidalis nasi, compressor nasi, dilatator naris, levator labii superioris alaeque nasi, and depressor labii superioris alaeque nasi. They have been already described with the muscles of the face.

3. The *Bones* of the nose are the nasal, and nasal processes of the superior maxillary.

4. The *Fibro-cartilages* give form and stability to the outwork of the nose, providing at the same time, by their elasticity, against injuries. They are five in number, namely, the—

   - Fibro-cartilage of the septum,
   - Two lateral fibro-cartilages,
   - Two alar fibro-cartilages.

The *Fibro-cartilage of the septum*, somewhat triangular in form, divides the nose into its two nostrils. It is connected above with the nasal bones and lateral fibro-cartilages; behind, with the ethmoidal septum and vomer; and below, with the palate processes of the superior maxillary bones. The alar fibro-cartilages and columna move freely upon the fibro-cartilage of the septum, being but loosely connected with it by perichondrium.

The *Lateral fibro-cartilages* are also triangular: they are connected, in front, with the fibro-cartilage of the septum; above with the nasal bones; behind with the nasal processes of the superior maxillary bones; and below with the alar fibro-cartilages.

*Alar fibro-cartilages.*—Each of these cartilages is curved in such a manner as to correspond with the opening of the nostril, to which it forms a kind of rim. The inner portion is loosely connected with the same part of the opposite cartilage, so as to form the columna. It is expanded and thickened at the point of the nose to constitute the lobe; and upon the side forms a curve corresponding with the form of the ala. This curve is prolonged downwards and forwards in the direction of the posterior border of the ala by three or four small fibro-cartilaginous plates, which are appendages to the alar fibro-cartilage.

---

* The fibro-cartilages of the nose. 1. One of the nasal bones. 2. The fibro-cartilage of the septum. 3. The lateral fibro-cartilage. 4. The alar fibro-cartilage. 5. The central portions of the alar fibro-cartilages which constitute the columna. 6. The appendix of the alar fibro-cartilage. 7. The nostrils.
The whole of these fibro-cartilages are connected with each other, and to the bones, by perichondrium, which, from its membranous structure, permits of the freedom of motion existing between them.

5. The Mucous membrane, lining the interior of the nose, is continuous with the skin externally, and with the pituitary membrane of the nasal fossae within. Around the entrance of the nostrils it is provided with numerous vibrissae.

6. Vessels and Nerves.—The Arteries of the nose are the lateralis nasi from the facial, and the nasalis septi from the superior coronary.

Its Nerves are the facial, infra-orbital, and nasal branch of the ophthalmic.

NASAL FOSÆ.

To obtain a good view of the nasal fossæ, the face must be divided through the nose by a vertical incision, a little to one side of the middle line.

The Nasal fossæ are two irregular, compressed cavities, extending backwards from the nose to the pharynx. They are bounded superiorly by the lateral cartilage and by the nasal, sphenoid and ethmoid bones; inferiorly by the hard palate; and in the middle line they are separated from each other by a bony and fibro-cartilaginous septum. A plan of the boundaries of the nasal fossae will be found at page 62.

Upon the outer wall of each fossa, in the dried skull, are three projecting processes, termed spongy bones. The two superior belong to the ethmoid, the inferior is a separate bone. In the fresh fossæ these are covered with mucous membrane, and serve to increase its surface by their prominence and by their convoluted form. The space intervening between the superior and middle spongy bone is the superior meatus; the space between the middle and inferior the middle meatus; and that between the inferior and the floor of the fossa the inferior meatus.

These meatuses are passages which extend from before backwards, and it is in rushing through and amongst these that the atmosphere deposits its odorant particles upon the mucous membrane. There are several openings into the nasal fossæ: thus, in the superior meatus are the openings of the sphenoidal and posterior ethmoidal cells; in the middle the anterior ethmoidal cells, the frontal sinuses, and the antrum maxillare; and, in the inferior meatus, the termination of the nasal duct. In the dried bone there are two additional openings, the sphenopalatine and the anterior palatine foramen; the former being situated in the superior, and the latter in the inferior meatus.

The Mucous membrane of the nasal fossæ is called pituitary, or Schneiderian.* The former name being derived from its secretion,

* Conrad Victor Schneider, professor of Medicine at Wittenberg. His work, entitled De Catarrhis, &c. was published in 1661.
the latter from Schneider, who was the first to show that the secretion of the nose proceeded from the mucous membrane, and not from the brain, as was formerly imagined. It is continuous with the general gastro-pulmonary mucous membrane, and may be traced through the openings in the meatuses, into the sphenoidal and ethmoidal cells; into the frontal sinuses; into the antrum maxillare; through the nasal duct to the surface of the eye, where it is continuous with the conjunctiva; along the Eustachian tubes into the tympanum and mastoid cells, to which it forms the lining membrane; and through the posterior nares into the pharynx and mouth, and thence through the lungs and alimentary canal.

The surface of this membrane is furnished with a columnar epithelium supporting innumerable vibratile cilia.

Vessels and Nerves.—The Arteries of the nasal fossae are the anterior and posterior ethmoidal, from the ophthalmic artery; and the spheno-palatine and pterygo-palatine from the internal maxillary.

The Nerves are, the olfactory, the spheno-palatine branches from Meckel's ganglion, and the nasal branch of the ophthalmic. The ultimate filaments of the olfactory nerve terminate in minute papillae.

THE EYE, WITH ITS APPENDAGES.

The form of the eyeball is that of a sphere, of about one inch in diameter, having the segment of a smaller sphere ingrafted upon its anterior surface, which increases its antero-posterior diameter. The axes of the two eyeballs are parallel with each other, but do not correspond with the axes of the orbits, which are directed outwards. The optic nerves follow the direction of the orbits, and therefore enter the eyeballs to their nasal side.

The Globe of the Eye is composed of tunics and of refracting media called humours. The tunics are three in number, the

1. Sclerotic and Cornea,
2. Choroid, Iris, and Ciliary processes,
3. Retina and Zonula ciliaris.

The humours are also three —

Aqueous,
Crystalline (lens),
Vitreous.

First Tunic. — The Sclerotic and Cornea form the external tunic of the eyeball, and give it its peculiar form. Four-fifths of the globe are invested by the sclerotic, the remaining fifth by the cornea.

The Sclerotic (σκληρός, hard) is a dense fibrous membrane, thicker behind than in front. It is continuous, posteriorly, with the sheath of the optic nerve, which is derived from the dura mater, and is pierced by that nerve as well as by the ciliary nerves and arteries.
Anteriorly it presents a bevelled edge which receives the cornea in the same way that a watch-glass is received by the groove in its case. Its anterior surface is covered by a thin tendinous layer, the tunica albuginea, derived from the expansion of the tendons of the four recti muscles. By its posterior surface it gives attachment to the two oblique muscles. The tunica albuginea is covered, for a part of its extent, by the mucous membrane of the front of the eye, the conjunctiva; and, by reason of the brilliancy of its whiteness, gives occasion to the common expression, "the white of the eye."

At the entrance of the optic nerve the sclerotic forms a thin cribriform lamella (lamina cribrosa), which is pierced by a number of minute openings for the passage of the nervous filaments. One of these openings, larger than the rest, and situated in the centre of the lamella, is the porus opticus, through which the arteria centralis retinae enters the eyeball.

---

* A longitudinal section of the globe of the eye. 1 The sclerotic, thicker behind than in front. 2. The cornea, received within the anterior margin of the sclerotic, and connected with it by means of a bevelled edge. 3. The choroid, connected anteriorly with (4) the ciliary ligament, and (5) the ciliary processes. 6. The iris. 7. The pupil. 8 The third layer of the eye, the retina, terminating anteriorly by an abrupt border at the commencement of the ciliary processes. 1. The canal of Petit, which encircles the lens (12); the thin layer in front of this canal is the zonula ciliaris, a prolongation of the vascular layer of the retina to the lens. 10. The anterior chamber of the eye, containing the aqueous humour: the lining membrane by which the humour is secreted is represented in the diagram. 11 The posterior chamber. 12. The lens, more convex behind than before, and enclosed in its proper capsule. 13. The vitreous humour enclosed in the hyaloid membrane, and in cells formed in its interior by that membrane. 14 A tubular sheath of the hyaloid membrane, which serves for the passage of the artery of the capsule of the lens. 15. The neurilemma of the optic nerve. 16. The arteria centralis retinae, embedded in the centre of the optic nerve.
The *Cornea* (corneus, horny) is the transparent projecting layer that constitutes the anterior fifth of the globe of the eye. In its form it is circular, concavo-convex, and resembles a watch-glass. It is received by its edge, which is sharp and thin, within the bevelled border of the sclerotic, to which it is very firmly attached, and it is somewhat thicker than the anterior portion of that tunic. When examined from the exterior, its vertical diameter is seen to be about one sixteenth shorter than the transverse, in consequence of the overlapping above and below, of the margin of the sclerotica; on the interior, however, its outline is perfectly circular.

The cornea is composed of four layers, namely, of the conjunctiva; of the cornea proper, which consists of several thin lamellae connected together by an extremely fine areolar tissue; of the cornea elastica, a "fine, elastic, and exquisitely transparent membrane, exactly applied to the inner surface of the cornea proper;" and of the liming membrane of the anterior chamber of the eyeball. The cornea elastica is remarkable for its perfect transparency, even when submitted for many days to the action of water or alcohol; while the cornea proper is rendered opaque by the same immersion. To expose this membrane, Dr. Jacob suggests that the eye should be placed in water for six or eight days, and then that all the opaque cornea should be removed layer after layer. Another character of the cornea elastica is its great elasticity, which causes it to roll up when divided or torn, in the same manner as the capsule of the lens. The use of this layer, according to Dr. Jacob, is to "preserve the requisite permanent correct curvature of the flaccid cornea proper."

The opacity of the cornea, produced by pressure on the globe, results from the infiltration of fluid into the areolar tissue connecting its layers. This appearance cannot be produced in a sound living eye.

**Dissection.**—The sclerotic and cornea are now to be dissected away from the second tunic; this, with care, may be easily performed, the only connections subsisting between them being at the circumference of the iris, the entrance of the optic nerve, and the perforation of the ciliary nerves and arteries. Pinch up a fold of the sclerotic near its anterior circumference, and make a small opening into it, then raise the edge of the tunic, and with a pair of fine scissors, having a probe point, divide the entire circumference of the sclerotic, and cut it away bit by bit. Then separate it from its attachment around the circumference of the iris by a gentle pressure with the edge of the knife. The dissection of the eye must be conducted under water.

In the course of this dissection the *ciliary nerves* and *long ciliary arteries* will be seen passing forwards between the sclerotic and choroid, to be distributed to the iris.

**Second Tunic.**—The second tunic of the eyeball is formed by the *choroid*, *ciliary ligament* and *iris*, the *ciliary processes* being an appendage developed from its inner surface.

The *Choroid* is a vascular membrane of a rich chocolate-brown

* The word *choroid* has been very much abused in anatomical language; it
colour upon its external surface, and of a deep black colour within. It is connected to the sclerotic, externally, by an extremely fine areolar tissue, and by nerves and vessels. Internally it is in simple contact with the third tunic of the eye, the retina. It is pierced posteriorly for the passage of the optic nerve, and is connected anteriorly with the iris, ciliary processes, and with the line of junction of the cornea and 'sclerotic, by a dense white structure, the ciliary ligament, which surrounds the circumference of the iris like a ring.

The choroid membrane is composed of three layers:—An external or venous layer, which consists principally of veins arranged in a peculiar manner: hence they have been named vena vorticosa. The marking upon the surface of the membrane produced by these veins, resembles so many centres, to which a number of curved lines converge. It is this layer which is connected with the ciliary ligament. The middle or arterial layer (tunica Ruyschiana*) is formed principally by the ramifications of minute arteries. It is reflected inwards at its junction with the ciliary ligament, so as to form the ciliary processes. The internal layer is a delicate membrane (membrana pigmenti) composed of several laminae of nucleated hexagonal cells, which contain the granules of pigmentum nigrum, and are arranged so as to resemble a tesselated pavement.

In animals the pigmentum nigrum, upon the posterior wall of the eyeball, is replaced by a layer of considerable extent, and of metallic brilliancy, called the tapetum.

The Ciliary ligament, or circle, is the bond of union between the external and middle tunics of the eyeball, and serves to connect the cornea and sclerotic, at their line of junction, with the iris and external layer of the choroid. It is also the point to which the ciliary nerves and vessels proceed previously to their distribution, and it receives the anterior ciliary arteries through the anterior margin of the sclerotic. A minute vascular canal is situated within the ciliary ligament, called the ciliary canal, or the canal of Fontana,† from its discoverer.

was originally applied to the membrane of the foetus called chorion from the Greek word χόριον, domicilium, that membrane being, as it were, the abode or receptacle of the foetus. Χόριον comes from χωρίω, to take or receive. Now it so happens that the chorion in the ovum is a vascular membrane of peculiar structure. Hence the term choroid, χώριον εἴδος, like the chorion, has been used indiscriminately to signify vascular structures, as in the choroid membrane of the eye, the choroid plexus, &c., and we find Cruveilhier in his admirable work on Anatomy, vol. iii. p. 463, saying in a note, "Choroïde est synonyme de vasculuse."

* Ruysch was born at the Hague in 1638, and was appointed professor of Anatomy at Amsterdam in 1665. His whole life was employed in making injected preparations, for which he is justly celebrated, and he died at the advanced age of ninety-three years. He came to the conclusion that the body was entirely made up of vessels.

† Felix Fontana, an anatomist of Tuscany. His "Description of a New Canal in the Eye," was published in 1778, in a Letter to the Professor of Anatomy in Upsal.
The Iris (iris, a rainbow,) is so named from its variety of colour in different individuals: it forms a septum between the anterior and posterior chambers of the eye, and is pierced somewhat to the nasal side of its centre by a circular opening, which is called the pupil. By its periphery it is connected with the ciliary ligament, and by its inner circumference forms the margin of the pupil; its anterior surface looks towards the cornea, and the posterior towards the ciliary processes and lens.

The iris is composed of two layers, an anterior or muscular, consisting of radiating fibres which converge from the circumference towards the centre, and have the power of dilating the pupil; and circular, which surround the pupil like a sphincter, and by their action produce contraction of its area. The posterior layer is of a deep purple tint, and is thence named uvea, from its resemblance in colour to a ripe grape.

The Ciliary processes may be seen in two ways, either by removing the iris from its attachment to the ciliary ligament, when a front view of the processes will be obtained, or by making a transverse section through the globe of the eye, when they may be examined from behind, as in fig. 154.

Fig. 154.*

The ciliary processes consist of a number of triangular folds, formed apparently by the plaiting of the middle and internal layer of the choroid. According to Zinn, they are about sixty in number, and

* The anterior segment of a transverse section of the globe of the eye, seen from within. 1. The divided edge of the three tunics; sclerotic, choroid (the dark layer), and retina. 2. The pupil. 3. The iris, the surface presented to view in this section being the uvea. 4. The ciliary processes. 5. The scalloped anterior border of the retina.
may be divided into large and small, the latter being situated in the spaces between the former. Their periphery is connected with the ciliary ligament, and is continuous with the middle and internal layer of the choroid. The central border is free, and rests against the circumference of the lens. The anterior surface corresponds with the uvea; the posterior receives the folds of the zonula ciliaris between its processes, and thus establishes a connection between the choroid and the third tunic of the eye. The ciliary processes are covered with a thick layer of pigmentum nigrum, which is more abundant upon them, and upon the anterior part of the choroid, than upon the posterior. When the pigment is washed off, the processes are of a whitish colour.

Third Tunic.—The third tunic of the eye is the retina, which is prolonged forwards to the lens by the zonula ciliaris.

Dissection.—If after the preceding dissection the choroid membrane be carefully raised and removed, the eye being kept under water, the retina may be seen very distinctly.

The Retina is composed of three layers:—

External or Jacob's membrane,
Middle, Nervous membrane,
Internal, Vascular membrane.

Jacob's membrane is extremely thin, and is seen as a flocculent film when the eye is suspended in water. Examined by the microscope, it is found to be composed of cells having a tesselated arrangement. Dr. Jacob considers it to be a serous membrane.

The Nervous membrane is the expansion of the optic nerve, and forms a thin semi-transparent bluish white layer, which envelopes the vitreous humour, and extends forwards to the commencement of the ciliary processes, where it terminates by an abrupt scalloped margin.

According to Treviranus, this layer is composed of cylindrical fibres, which proceed from the optic nerve and bend abruptly inwards, near their termination, to form the internal papillary layer, which lies in contact with the hyaloid membrane; each fibre constituting by its extremity a distinct papilla.

The Vascular membrane consists of the ramifications of a minute artery, the arteria centralis retinae, and its accompanying vein; the artery pierces the optic nerve, and enters the globe of the eye through the porus opticus, in the centre of the lamina cribrosa. This artery may be seen very distinctly by making a transverse section of the eyeball. Its branches are continuous anteriorly with the zonula ciliaris. The vascular layer forms distinct sheaths for the nervous papillae, which constitute the inner surface of the retina.

In the centre of the posterior part of the globe of the eye the retina presents a circular spot, which is called the foramen of Soemmering;*

* Samuel Thomas Soemmering is celebrated for the beautiful and accurate
it is surrounded by a yellow halo, the *limbus luteus*, and is frequently obscured by an elliptical fold of the retina, which, from its constancy of appearance, has been regarded as a normal condition of the membrane. The term foramen is misapplied to this spot, for the vascular layer and the *membrana Jacobi* are continued across it; the nervous substance alone appearing to be deficient. It exists only in animals having the axis of the eyeballs parallel with each other, as man, quadrumana, and some saurian reptiles, and is said to give passage to a small lymphatic vessel.

The *Zonula ciliaris* (zonula of Zinn)† is a thin vascular layer, which connects the anterior margin of the retina with the anterior surface of the lens near its circumference. It presents upon its surface a number of small folds corresponding with the ciliary processes, between which they are received. These processes are arranged in the form of rays around the lens, and the spaces between them are

plates which accompany his works. The account "De Foramine Centrallī Retīnae Humanae, Limbo Luteo cincto," was published in 1779, in the *Commentationes Soc. Reg. Scient. Gottingensis*.

† John Gottfried Zinn, professor of Anatomy in Göttingen; his "*Descriptio Anatomica Oculī Humani,*" was published in 1755; with excellent plates. It was republished by Wrisberg in 1780.
stained by the pigmentum nigrum of the ciliary processes. They derive their vessels from the vascular layer of the retina. The under surface of the zonula is in contact with the hyaloid membrane, and around the lens forms the anterior fluted wall of the canal of Petit.

The connection between these folds and the ciliary processes may be very easily demonstrated by dividing an eye transversely into two portions, then raising the anterior half, and allowing the vitreous humour to separate from its attachment by its own weight. The folds of the zonula will then be seen to be drawn out from between the folds of the ciliary processes.

_Humours._—The _Aqueous humour_ is situated in the anterior and posterior chambers of the eye; it is a weakly albuminous fluid, having an alkaline reaction, and a specific gravity very little greater than distilled water. According to Petit, it scarcely exceeds four or five grains in weight.

The _anterior chamber_ is the space intervening between the cornea in front, and the iris and pupil behind. The _posterior chamber_ is the narrow space, less than half a line in depth,* bounded by the posterior surface of the iris and pupil in front, and by the ciliary processes, zonula ciliaris, and lens behind. The two chambers are lined by a thin layer, the _secreting membrane of the aqueous humour._

The _Vitreous humour_ forms the principal bulk of the globe of the eye. It is an albuminous fluid resembling the aqueous humour enclosed in a delicate membrane, the _hyaloid_, which sends processes into its interior, forming areolae in which the humour is retained. A small artery may sometimes be traced through the centre of the vitreous humour to the capsule of the lens; it is surrounded by a tubular sheath of the hyaloid membrane. This vessel is easily injected in the foetus.

The _Crystalline humour_ or _lens_ is situated immediately behind the pupil, and is surrounded by the ciliary processes which slightly overlap its margin. It is more convex on the posterior than on the anterior surface, and is embedded in the anterior part of the vitreous humour, from which it is separated by the hyaloid membrane. It is invested by a peculiarly transparent and elastic membrane, the capsule of the lens, which contains a small quantity of fluid called _liquor Morgagni_,† and is retained in its place by the attachment of the zonula ciliaris. Dr. Jacob is of opinion that the lens is connected to its capsule by means of areolar tissue, and that the liquor Morgagni is the result of a cadaveric change.

The lens consists of concentric layers, of which the external are

---

* Winslow and Lieutaud thought the iris to be in contact with the lens; it frequently adheres to the capsule of the latter in iritis. The depth of the posterior chamber is greater in old than in young persons.

† John Baptist Morgagni was born in 1682. He was appointed Professor of Medicine in Bologna, and published the first part of his "_Adversaria Anatomica_," in 1706. He died in 1771.
soft, the next firmer, and the central form a hardened nucleus. These layers are best demonstrated by boiling, or by immersion in alcohol, when they separate easily from each other. Another division of the lens takes place at the same time: it splits into three triangular segments, which have the sharp edge directed towards the centre, and the base towards the circumference. The concentric lamellae are composed of minute parallel fibres, which are united with each other by means of scalloped borders; the convexity on the one border fitting accurately the concave scallop upon the other.

Immediately around the circumference of the lens is a triangular canal, the *canal of Petit,* about a line and a half in breadth. It is bounded in front by the flutings of the zonula ciliaris; behind by the hyaloid membrane; and within by the border of the lens.

The *Vessels* of the globe of the eye are the long, and short, and anterior ciliary arteries, and the arteria centralis retinae. The *long ciliary arteries,* two in number, pierce the posterior part of the sclerotic, and pass forward on each side, between that membrane and the choroid, to the ciliary ligament, where they divide into two branches, which are distributed to the iris. The *short ciliary arteries* pierce the posterior part of the sclerotic coat, and are distributed to the middle layer of the choroid membrane. The *anterior ciliary* are branches of the muscular arteries. They enter the eye through the anterior part of the sclerotic, and are distributed to the iris. It is the increased number of these latter arteries in iritis that gives rise to the peculiar red zone around the circumference of the cornea.

The *arteria centralis retinae* enters the optic nerve at about half an inch from the globe of the eye, and passing through the porus opticus is distributed upon the inner surface of the retina, forming its vascular layer; one branch pierces the centre of the vitreous humour, and supplies the capsule of the lens.

The *Nerves* of the eyeball are the optic, two ciliary nerves from the nasal branch of the ophthalmic, and the ciliary nerves from the ciliary ganglion.

**Observations.**—The sclerotic is a tunic of protection, and the cornea a medium for the transmission of light. The choroid supports the vessels destined for the nutrition of the eye, and by its pigmentum nigrum absorbs all loose and scattered rays that might confuse the image impressed upon the retina. The iris, by means of its powers of expansion and contraction, regulates the quantity of light admitted through the pupil. If the iris be thin, and the rays of light pass through its substance, they are immediately absorbed by the uvea; and if that layer be insufficient, they are taken up by the black pigment of the ciliary processes. In Albinoes, where there is an absence of pigmentum nigrum, the rays of light traverse the iris and even the sclerotic, and so overwhelm the eye with light, that sight is destroyed,

* John Louis Petit, a celebrated French surgeon: he published several surgical and anatomical Essays, in the early part of the 18th century. He died in 1750.
except in the dimness of evening or at night. In the manufacture of optical instruments care is taken to colour their interior black with the same object, the absorption of scattered rays.

The transparent lamellated cornea and the humours of the eye have for their office the refraction of the rays in such proportion as to direct the image in the most favourable manner upon the retina. Where the refracting medium is too great, as in over convexity of the cornea and lens, the image falls short of the retina (myopia, near-sightedness); and where it is too little the image is thrown beyond the nervous membrane (presbyopia, far-sightedness). These conditions are rectified by the use of spectacles, which provide a differently refracting medium externally to the eye, and thereby correct the transmission of light.

**APPENDAGES OF THE EYE.**

The *Appendages of the eye* (*tutamina oculi*) are the eyebrows, eyelids, eyelashes, conjunctiva, caruncula lachrymalis, and the lachryma apparatus.

The *Eyebrows* (*superclilia*) are two projecting arches of integument covered with short thick hairs, which form the upper boundary of the orbits. They are connected beneath with the orbiculares, occipitofrontales, and corrugatores superciliorum muscles; their use is to shade the eyes from a too vivid light, or protect them from particles of dust and moisture floating over the forehead.

The *Eyelids* (*palpebrae*) are two valvular layers placed in front of the eye, serving to defend it from injury by their closure. When drawn open they leave between them an elliptical space, the angles of which are called *canthi*. The outer canthus is formed by the meeting of the two lids at an acute angle. The inner canthus is prolonged for a short distance inwards towards the nose, and a triangular space is left between the lids in this situation, which is called the *lacus lachrymalis*. At the commencement of the lacus lachrymalis upon each of the two lids is a small angular projection, the *lachrymal papilla* or *tubercle*; and at the apex of each papilla a small orifice (*punctum lachrymale*), the commencement of the lachrymal canal.

The eyelids have, entering into their structure, *integument*, *orbicularis muscle*, *tarsal cartilages*, *Meibomian glands*, and *conjunctiva*.

The tegumentary areolar tissue of the eyelids is remarkable for its looseness and for the entire absence of adipose substance; it is particularly liable to serous infiltration. The fibres of the orbicularis muscle covering the eyelids, are extremely thin and pale.

The *Tarsal cartilages* are two thin lamellæ of fibro-cartilage about an inch in length, which give form and support to the eyelids. The *superior* is of a semilunar form, about one-third of an inch in breadth at its middle, and tapering to each extremity. Its lower border is broad and flat, its upper is thin, and gives attachment to the levator palpebrae and to the fibrous membrane of the lids.
The *Inferior fibro-cartilage* is an elliptical band, narrower than the superior, and situated in the substance of the lower lid. Its upper border is flat, and corresponds with the flat edge of the upper cartilage. The lower is held in its place by the fibrous membrane. At the inner canthus the tarsal cartilages terminate at the commencement of the lacus lachrymalis, and are attached to the margin of the orbit by the tendo oculi. At their outer extremity they terminate at a short distance from the angle of the canthus, and are retained in their position by means of a decussation of the fibrous structure of the broad tarsal ligament, called the *external palpebral ligament*.

The *Fibrous membrane* of the lids is firmly attached to the perios-teum, around the margin of the orbit, by its circumference, and to the tarsal cartilages by its central margin. It is thick and dense on the outer half of the orbit, but becomes thin to its inner side. Its use is to retain the tarsal cartilages in their place, and give support to the lids; hence it has been named the *broad tarsal ligament*.

The *Meibomian glands* are embedded in the internal surface of the cartilages, and are very distinctly seen on examining the inner aspect of the lids. They have the appearance of parallel strings of pearls, about thirty in number in the upper cartilage, and somewhat fewer in the lower; they open by minute foramina upon the edges of the lids. They correspond in length with the breadth of the cartilage, and are consequently longer in the upper than in the lower lid.

Each gland consists of a single lengthened follicle or tube, into which a number of small clustered follicles open; the latter are so numerous as almost to conceal the tube by which the secretion is poured out upon the margin of the lids. Occasionally an arch is formed between two of them, and produces a very graceful appearance.

The edges of the eyelids are furnished with a triple row of long thick hairs, which curve upwards from the upper lid, and downwards from the lower, so that they may not interlace with each other in the closure of the eyelids, and prove an impediment to the opening of the eyes. These are the *eyelashes (cilia)*, important organs of defence to the sensitive surface of so delicate an organ as the eye.

The *Conjunctiva* is the mucous membrane of the eye. It covers the whole of its anterior surface, and is then reflected upon the lids so as to form their internal layer. The duplicatures formed between the globe of the eye and the lids are called the *superior and inferior palpebral sinuses*, of which the former is much deeper than the inferior. Where it covers the cornea the conjunctiva is very thin and closely adherent, and no vessels can be traced into it. Upon the sclerotica it is thicker and less adherent, but upon the inner surface of the lids is very closely connected, and is exceedingly vascular. It is continuous with the general gastro-pulmonary mucous membrane and sympathises in its affections, as may be observed in various diseases. From the surface of the eye it may be traced through the lachrymal ducts into

*Henry Meibomius, "de Vasis Palpebrarum Novis," 1666.*
the lachrymal gland; along the edges of the lids it is continuous with the mucous lining of the Meibomian glands, and at the inner angle of the eye may be followed through the lachrymal canals into the lachrymal sac, and thence downwards through the nasal duct into the inferior meatus of the nose.

The Caruncula lachrymalis is the small reddish body which occupies the lacus lachrymalis at the inner canthus of the eye. In health it presents a bright pink tint; in sickness it loses its colour and becomes pale. It consists of an assemblage of follicles similar to the Meibomian glands, embedded in a fibro-cartilaginous tissue, and is the source of the whitish secretion which so constantly forms at the inner angle of the eye. It is covered with minute hairs which are sometimes so long as to be distinctly visible to the naked eye.

Immediately to the outer side of the caruncula is a slight duplicature of the conjunctiva, called plica semilunaris, which contains a minute plate of cartilage, and is the rudiment of the third lid of animals, the membrana nictitans of birds.

Vessels and nerves. — The palpebrae are supplied internally with arteries from the ophthalmic, and externally from the facial and transverse facial. Their nerves are branches of the fifth and of the facial.

LACHRYMAL APPARATUS.

The Lachrymal apparatus consists of the lachrymal gland with its excretory ducts; the puncta lachrymalia, and lachrymal canals; the lachrymal sac and nasal duct.

The Lachrymal gland is situated at the upper and outer angle of the orbit, and consists of two portions, orbital and palpebral. The orbital portion, about three quarters of an inch in length, is flattened and oval in shape, and occupies the lachrymal fossa in the orbital plate of the frontal bone. It is in contact superiorly with the perios- teum, with which it is closely connected by its upper and convex surface; by its inferior or concave surface it is in relation with the globe of the eye, and the superior and external rectus; and by its anterior border with the broad tarsal ligament. By its posterior border it receives its vessels and nerves. The palpebral portion, smaller than the preceding, is situated in the upper eyelid, extending downwards to the superior margin of the tarsal cartilage. It is continuous with the orbital portion above, and is enclosed in an investment of dense fibrous membrane. The secretion of the lachrymal gland is conveyed away by ten or twelve small ducts which run for a short distance beneath the conjunctiva, and open upon its surface by a series of pores about one-twentieth of an inch apart, situated in a curved line a little above the upper border of the tarsal cartilage.

Lachrymal canals. — The lachrymal canals commence at the minute openings, puncta lachrymalia, seen upon the lachrymal papillae of the lids at the outer extremity of the lacus lachrymalis, and proceed in-
wards to the lachrymal sac, where they terminate beneath a valvular semilunar fold of the lining membrane of the sac. The *superior* duct at first ascends, and then turns suddenly inwards towards the sac, forming an abrupt angle. The *inferior* duct forms the same kind of angle, by descending at first, and then turning abruptly inwards. They are dense and elastic in structure, and remain constantly open, so that they act like capillary tubes in absorbing the tears from the surface of the eye. The two fasciculi of the tensor tarsi muscle are inserted into these ducts, and serve to draw them inwards.

The *Lachrymal sac* is the upper extremity of the nasal duct, and is scarcely more dilated than the rest of the canal. It is lodged in the groove of the lachrymal bone, and is often distinguished internally from the nasal duct by a semilunar or *circular valve*. The sac consists of mucous membrane, but is covered in and retained in its place by a fibrous expansion, derived from the tendon of the orbicularis, which is inserted into the ridge on the lachrymal bone; it is also covered by the tensor tarsi muscle, which arises from the same ridge, and in its action upon the lachrymal canals may serve to compress the lachrymal sac.

The *Nasal duct* is a short canal about three quarters of an inch in length, directed downwards, backwards, and a little outwards to the inferior meatus of the nose, where it terminates by an expanded orifice. It is lined by mucous membrane, which is continuous with the conjunctiva above, and with the pituitary membrane of the nose below. Obstruction from inflammation and suppuration of this duct constitutes the disease called fistula lachrymalis.

*Vessels and nerves.* — The lachrymal gland is supplied with blood by the lachrymal branch of the ophthalmic artery, and with nerves by the lachrymal branch of the ophthalmic and orbital branch of the *superior maxillary*.

**THE ORGAN OF HEARING.**

The apparatus of hearing is composed of three parts; the external ear, middle ear or tympanum, and internal ear or labyrinth.

The *External ear* consists of two portions, the *pinna* and *meatus*; the former representing a kind of funnel which collects the vibrations of the atmosphere, called sounds, and the latter a tube which conveys the vibrations to the tympanum.

The *Pinna* presents a number of folds and hollows upon its surface, which have different names assigned to them. Thus the external folded margin is called the *helix* (*ἰλιξ*, a fold). The elevation parallel to and in front of the helix is called *anthelix* (*ἄννυς*, opposite). The pointed process, projecting like a valve over the opening of the ear from the face, is called the *tragus* (*τράγος*, a goat), probably from being sometimes covered with bristly hair like that of a goat; and a tubercle opposite to this is the *antitragus*. The lower dependent and
fleshy portion of the pinna, is the lobulus. The space between the helix and antihelix is named the fossa innominata. Another depression is observed at the upper extremity of the antihelix, which bifurcates and leaves a triangular space between its branches called the scaphoid fossa; and the large central space to which all the channels converge is the concha, which opens directly into the meatus.

The pinna is composed of integument, fibro-cartilage, ligaments, and muscles.

The Integument is thin, contains an abundance of sebaceous follicles, and is closely connected with the fibro-cartilage.

The Fibro-cartilage gives form to the pinna, and is folded so as to produce the various convexities and grooves which have been described upon its surface. The helix commences in the concha, and partially divides that cavity into two parts; on its anterior border is a tubercle for the attachment of the attrahens aurum muscle, and a little above this a small vertical fissure, the fissure of the helix. The termination of the helix and antihelix forms a lengthened process, the processus caudatus, which is separated from the concha by an extensive fissure. Upon the anterior surface of the tragus is another fissure, the fissure of the tragus, and in the lobulus the fibro-cartilage is wholly deficient. The fibro-cartilage of the meatus, at the upper and anterior part of the cylinder, is divided from the concha by a fissure which is closed in the entire ear by ligamentous fibres; it is firmly attached at its termination to the processus auditorius.

The Ligaments of the external ear are those which attach the pinna to the side of the head, viz. the anterior, posterior, and ligament of the tragus; and those of the fibro-cartilage which serve to preserve its folds and connect the opposite margins of the fissures. The latter are two in number, the ligament between the concha and the processus caudatus, and the broad ligament which extends from the upper margin of the fibro-cartilage of the tragus to the helix, and completes the meatus.

The proper Muscles of the pinna are the—

Major helicis,
Minor helicis,
Tragicus,
Antitragicus,
Transversus auriculæ.

The Major helicis is a narrow band of muscular fibres situated upon the anterior border of the helix, just above the tragus.

The Minor helicis is placed upon the posterior border of the helix, at its commencement in the fossa of the concha.

The Tragicus is a thin quadrilateral layer of muscular fibres, situated upon the tragus.

The Antitragicus arises from the antitragus, and is inserted into the posterior extremity, or processus caudatus of the helix.
MEATUS AUDITORIUS.—TYMPANUM.

The Transversus auriculae, partly tendinous and partly muscular, extends transversely from the convexity of the concha to that of the helix, on the posterior surface of the pinna. These muscles are rudimentary in the human ear, and deserve only the title of muscles in the ears of animals. Two other muscles are described by Mr. Tod,* the obliquus auris and contractor meatus, or trago-helicus.

The Meatus auditorius is a canal, partly cartilaginous and partly osseous, about an inch in length, which extends inwards and a little forwards from the concha to the tympanum. It is narrower in the middle than at each extremity, forms an oval cylinder, the long diameter being vertical, and is slightly curved upon itself, the concavity looking downwards.

It is lined by an extremely thin pouch of epidermis, which, when withdrawn after maceration, preserves the form of the meatus. Some stiff short hairs are also found in its interior, which stretch across the tube, and prevent the ingress of insects and dust. Beneath the epidermis are a number of small ceruminous follicles, which secrete the wax of the ear.

Vessels and Nerves.—The pinna is plentifully supplied with arteries; by the anterior auricular from the temporal, and by the posterior auricular from the external carotid.

Its Nerves are derived from the anterior auricular of the fifth, the posterior auricular of the facial, and the auricularis magnus of the cervical plexus.

MIDDLE EAR OR TYMPANUM.

The tympanum is an irregular bony cavity, compressed from without inwards, and situated within the petrous bone. It is bounded externally by the meatus and membrana tympani; internally by the base of the petrous bone; and in its circumference by the petrous bone and mastoid cells.

The Membrana tympani is a thin and semi-transparent membrane of an oval shape, the long diameter being vertical. It is inserted into a groove around the circumference of the meatus near its termination, and is placed obliquely across the area of that tube, the direction of the obliquity being downwards and inwards. It is concave towards the meatus, and convex towards the tympanum, and is composed of three layers, an external epidermic, middle fibrous and muscular, and internal mucous, derived from the mucous lining of the tympanum.

The tympanum contains three small bones, ossicula auditis, viz., the malleus, incus, and stapes.

* "The Anatomy and Physiology of the Organ of Hearing," by David Tod, 1832.
The Malleus (hammer) consists of a head, neck, handle (manubrium), and two processes, long (processus gracilis), and short (processus brevis). The manubrium is connected to the membrana tympani by its whole length extending to below the central point of that membrane. It lies beneath its mucous layer, and serves as a point of attachment to which the radiating fibres of the fibrous layer converge. The long process descends to a groove near the fissura Glaseri, and gives attachment to the laxator tympani muscle. Into the short process is inserted the tendon of the tensor tympani, and the head of the bone articulates with the incus.

* A diagram of the ear. p. The pinna. t. The tympanum. l. The labyrinth. 1. The upper part of the helix. 2. The antihelix. 3. The tragus. 4. The antitragus. 5. The lobulus. 6. The concha. 7. The upper part of the fossa innominata. 8. The meatus. 9. The membrana tympani, divided by the section. 10. The three little bones, crossing the area of the tympanum, malleus, incus, and stapes; the foot of the stapes blocks up the fenestra ovalis upon the inner wall of the tympanum. 11. The promontory. 12. The fenestra rotunda; the dark opening above the ossicula leads into the mastoid cells. 13. The Eustachian tube; the little canal upon this tube contains the tensor tympani muscle in its passage to the tympanum. 14. The vestibule. 15. The three semicircular canals, horizontal, perpendicular and oblique. 16. The ampullae upon the perpendicular and horizontal canals. 17. The cochlea. 18. A depression between the convexities of the two tubuli which communicate with the tympanum and vestibule; the one is the scala tympani, terminating at 12; the other is the scala vestibuli.
The *Incus* (*anvil*) is named from an imagined resemblance to an anvil. It has also been likened to a bicuspid tooth, having one root longer than, and widely separated from the other. It consists of two processes, which unite nearly at right angles, and at their junction form a flattened body, to articulate with the head of the malleus. The short process is attached to the margin of the opening of the mastoid cells by means of a short ligament; the long process descends nearly parallel with the handle of the malleus, and curves inwards, near its termination. At its extremity is a small globular projection, the *os orbiculare*, which in the foetus is a distinct bone, but becomes anchylosed to the long process of the incus in the adult; this process articulates with the head of the stapes.

The *Stapes* is shaped like a stirrup, to which it bears a close resemblance. Its head articulates with the *os orbiculare*, and the two branches are connected by their extremities with a flat oval-shaped plate, representing the foot of the stirrup. The foot of the stirrup is received into the fenestra ovalis, to the margin of which it is connected by means of a circular ligament; it is in contact, by its surface, with the membrana vestibuli, and is covered in by the mucous lining of the tympanum. The neck of the stapes gives attachment to the stapedius muscle.

The ossicula auditus are retained in their position and moved upon themselves by means of ligaments and muscles.

The *Ligaments* are three in number; the ligament of the head of the malleus, which is attached superiorly to the upper wall of the tympanum; the ligament of the incus, a short and thick band, which serves to attach the extremity of the short process of that bone to the margin of the opening of the mastoid cells; and the circular ligament which connects the margin of the foot of the stapes with the circumference of the fenestra ovalis. These ligaments have been described as muscles, by Mr. Tod, under the names of superior capitis mallei, obliquus incudis externus posterior, and musculus vel structura stapedii inferior.

The *Muscles of the tympanum* are four in number, the—

- Tensor tympani,
- Laxator tympani,
- Laxator tympani minor,
- Stapedius.

The *Tensor tympani* (*musculus internus mallei*) *arises* from the spinous process of the sphenoid, from the petrous portion of the temporal bone, and from the Eustachian tube, and passes forwards in a distinct canal, separated from the tube by the processus cochleariformis, to be *inserted* into the handle of the malleus, immediately below the commencement of the processus gracilis.

The *Laxator tympani* (*musculus externus mallei*) *arises* from the
spinous process of the sphenoid bone, and passes through an opening in the fissura Glaseri, to be inserted into the long process of the malleus. This is regarded as a ligament by some anatomists.

The Laxator tympani minor arises from the upper margin of the meatus, and is inserted into the handle of the malleus, near the processus brevis. This is regarded as a ligament by some anatomists.

The Stapedius arises from the interior of the pyramid, and escapes from its summit to be inserted into the neck of the stapes.

Foramina.—The openings in the tympanum are ten in number, five large and five small; they are—

</table>

The opening of the meatus auditorius has been previously described. The Fenestra ovalis (fenestra vestibuli), is a reiform opening, situated at the bottom of a small oval fossa (the pelvis ovalis), in the upper part of the inner wall of the tympanum, directly opposite the meatus. The long diameter of the fenestra is directly horizontally, and its convex borders upwards. It is the opening of communication between the tympanum and the vestibule, and is closed by the foot of the stapes and by the lining membranes of both cavities.

The Fenestra rotunda (fenestra cochleæ) is somewhat triangular in its form, and situated in the inner wall of the tympanum, below and rather posteriorly to the fenestra ovalis, from which it is separated by a bony elevation, called the promontory. It serves to establish a communication between the tympanum and the cochlea. In the fresh subject it is closed by a proper membrane (m. tympani secundaria), as well as by the lining of both cavities.

The Mastoid cells are numerous, and occupy the whole of the interior of the mastoid process, and part of the petrous bone. They communicate by a large irregular opening with the upper and posterior circumference of the tympanum.

The Eustachian tube is a canal of communication extending obliquely between the pharynx and the anterior circumference of the tympanum. In structure it is partly fibro-cartilaginous and partly osseous, is broad and expanded at its pharyngeal extremity, and narrow and compressed at the tympanum.

The smaller openings serve for the transmission of the chorda tympani nerve, and three of the muscles of the tympanum.

The opening by which the chorda tympani enters the tympanum, is near the root of the pyramid, at about the middle of the posterior wall.
The opening of exit for the *chorda tympani* is at the fissura Glaseri in the anterior wall of the tympanum.

The opening for the *laxator tympani muscle* is also situated in the fissura Glaseri, in the anterior wall of the tympanum.

The opening for the *tensor tympani muscle* is in the inner wall, immediately above the opening of the Eustachian tube.

The opening for the *stapedius muscle* is at the apex of a conical bony eminence, called the pyramid, which is situated on the posterior wall of the tympanum, immediately behind the fenestra ovalis.

Directly above the fenestra ovalis is a rounded ridge formed by the projection of the *aquaeductus Fallopii*.

Beneath the fenestra ovalis and separating it from the fenestra rotunda is the *promontory*, a rounded prominence formed by the projection of the first turn of the cochlea. It is channeled upon its surface by three small grooves, which lodge the three tympanic branches of Jacobson’s nerve.

The Foramina and processes of the tympanum may be arranged, according to their situation, into four groups.

1. In the External wall is the *meatus auditorius*, closed by the *membrana tympani*.
2. In the Inner wall, from above downwards, are the—
   - Opening for the tensor tympani,
   - Ridge of the *aquaeductus Fallopii*,
   - Fenestra ovalis,
   - Promontory,
   - Grooves for Jacobson’s nerve,
   - Fenestra rotunda.
3. In the Posterior wall are the—
   - Opening of the mastoid cells
   - Pyramid,
   - Opening for the stapedius,
   - Opening for Jacobson’s nerve,
   - Apertura chordae (entrance).
4. In the Anterior wall are the—
   - Eustachian tube,
   - Fissura Glaseri,
   - Opening for the laxator tympani,
   - Apertura chordae (exit).

The tympanum is lined by a *vascular mucous membrane*, which invests the ossicula and chorda tympani, and forms the internal layer of the membrana tympani. From the tympanum it is reflected into the
Vessels and Nerves.—The Arteries of the tympanum are derived from the internal maxillary, internal carotid, and posterior auricular.

Its Nerves are—1. Minute branches from the facial, which are distributed to the stapedius muscle. 2. The chorda tympani, which leaves the facial nerve near the stylo-mastoid foramen, and arches upwards to enter the tympanum at the root of the pyramid; it then passes forwards between the handle of the malleus and long process of the incus, to its proper opening in the fissura Glaseri. 3. The tympanic branches of Jacobson's nerve, which are distributed to the membranes of the fenestra ovalis and fenestra rotunda, and to the Eustachian tube, and form a plexus by communicating with the carotid plexus, otic ganglion, and Vidian nerve. 4. A filament from the otic ganglion to the tensor tympani muscle.

INTERNAL EAR.

The Internal ear is called labyrinth, from the complexity of its communications; it consists of a membranous and an osseous portion. The osseous labyrinth presents a series of cavities which are channeled through the substance of the petrous bone, and is situated between the cavity of the tympanum and the meatus auditorius internus. It is divisible into the—

Vestibule,
Semicircular canals,
Cochlea.

The Vestibule is a small three-cornered cavity, compressed from without inwards, and situated immediately within the inner wall of the tympanum. The three corners which are named ventricles or cornua are placed, one anteriorly, one superiorly, and one posteriorly.

The Anterior ventricle receives the oval aperture of the scala vestibuli; the superior, the ampullary openings of the superior and horizontal semicircular canals; the posterior ventricle receives the ampullary opening of the oblique semicircular canal, the common aperture of the oblique and perpendicular canals, the termination of the horizontal canal, and the aperture of the aqueductus vestibuli. In the anterior ventricle is a small depression, which corresponds with the posterior segment of the cul de sac of the meatus auditorius internus; it is called the fovea hemispherica, and is pierced by a cluster of small openings, the macula cribrosa. In the superior ventricle of the vestibule is another small depression, the fovea elliptica, which is separated from the fovea hemispherica by a projecting crest, the eminentia pyramidalis. The latter is pierced by numerous minute openings for
the passage of nervous filaments. The posterior ventricle presents a third small depression, the fovea sulciformis, which leads upwards to the ostium aqueductus vestibuli. The internal wall of the vestibule corresponds with the bottom of the cul de sac of the meatus auditorius internus, and is pierced by numerous small openings for the transmission of nervous filaments. In the external or tympanic wall is the reniform opening of the fenestra ovalis (fenestra vestibuli), the margin of which presents a prominent rim towards the cavity of the vestibule.

The openings of the vestibule may be arranged, like those of the tympanum, into large and small.

The Large openings are seven in number; viz. the—

- Fenestra ovalis,
- Scala vestibuli,
- Five openings of the three semicircular canals.

The Small openings are the—

- Aquaeductus vestibuli,
- Openings for small arteries,
- Openings for branches of the auditory nerve.

The Fenestra ovalis has already been described; it is the opening into the tympanum.

The opening of the scala vestibuli is the oval termination of the vestibular canal of the cochlea.

The Aquaeductus vestibuli (canal of Cotunnius) is the commencement of the small canal which opens under the osseous scale upon the posterior surface of the petrous bone. It gives passage to a process of membrane which is continuous internally with the lining membrane of the vestibule, and externally with the dura mater, and to a small vein.

The Openings for the arteries and nerves are situated in the internal wall of the vestibule, and correspond with the termination of the meatus auditorius internus.

The Semicircular canals are three bony passages communicating with the vestibule, into which they open by both extremities. Near one extremity of each of the canals is a remarkable dilatation of its cavity, which is called the ampulla (sinus ampullaceus). The superior, or perpendicular canal (canalis semicircularis verticalis superior), is directed transversely across the petrous bone, forming a projection upon the anterior face of the latter. It commences by means of an ampulla in the superior ventricle of the vestibule, and terminates posteriorly by joining with the oblique, and forming a common canal, which opens into the upper part of the posterior ventricle. The middle or oblique canal (canalis semicircularis verticalis posterior) corresponds with the posterior part of the petrous portion of the temporal
bone: it commences by an ampullary dilatation in the posterior ventricle, and curves nearly perpendicularly upwards to terminate in the common canal. In the ampulla of this canal are numerous minute openings for nervous filaments. The inferior or horizontal canal (canalis semicircularis horizontalis) is directed outwards towards the base of the petrous bone, and is shorter than the two preceding. It commences by an ampullary dilatation in the superior ventricle, and terminates in the posterior ventricle.

The Cochlea (snail shell) forms the anterior portion of the labyrinth, corresponding by its apex with the anterior wall of the petrous bone, and by its base with the anterior depression at the bottom of the cul de sac of the meatus auditorius internus. It consists of an osseous and gradually tapering canal, about one inch and a half in length, which makes two turns and a half spirally around a central axis called the modiolus.

The central axis or modiolus is large near its base where it corresponds with the first turn of the cochlea, and diminishes in diameter towards its extremity. At its base it is pierced by numerous minute openings which transmit the filaments of the cochlear nerve. These openings are disposed in a spiral manner: hence they have received from Cotunnius† the name of tractus spiralis foraminu-

* The cochlea divided parallel with its axis, through the centre of the modiolus. After Breschet. 1. The modiolus. 2. The infundibulum in which the modiolus terminates. 3, 3. The cochlear nerve, sending its filaments through the centre of the modiolus. 4, 4. The scala tympani of the first turn of the cochlea. 5, 5. The scala vestibuli of the first turn; the septum between 4 and 5 is the lamina spiralis; a filament of the cochlear nerve is seen passing between the layers of the lamina to be distributed upon the membrane which invests the lamina. 7. The membranous portion of the lamina spiralis. 8. Loops formed by the filaments of the cochlear nerve on the lamina spiralis. 9, 9. Scala tympani of the second turn of the cochlea. 10, 10. Scala vestibuli of the second turn; the septum between the two is the lamina spiralis. 11. The remaining half turn of the scala vestibuli; the dome placed over this half turn is the cupola; a line leads from the numeral to the remaining half turn of the scala tympani. The lamina of bone which forms the floor of the scala vestibuli curves spirally round to constitute the infundibulum (2). 14. The helicotrema through which a bristle is passed; its lower extremity issues from the scala tympani of the middle turn of the cochlea.

† Dominico Cotumnus, an Italian physician; his dissertation “De Aqueductibus Auris Humanæ Internæ” was published at Naples in 1761.
lentus. The modiolus is everywhere traversed in the direction of its length by minute canals, which proceed from the tractus spiralis foraminulentus, and terminate upon the sides of the modiolus, by opening into the canal of the cochlea or upon the surface of its lamina spiralis. The central canal of the tractus spiralis foraminulentus is larger than the rest, and is named the tubulus centralis modioli; it is continued onwards to the extremity of the modiolus, and transmits a nerve and small artery, the arteria centralis modioli.

The interior of the canal of the cochlea is partially divided into two passages (scalae) by means of a thin and porous lamina of bone (zonula ossea laminae spiralis), which is wound spirally around the modiolus in the direction of the canal. This bony septum extends for about two-thirds across the diameter of the canal, and in the fresh subject is prolonged to the opposite wall by means of a membranous layer, so as to constitute a complete partition, the lamina spiralis. The osseous lamina spiralis consists of two thin lamellae of bone, between which, and through the perforations on their surfaces, the filaments of the cochlear nerve reach the membrane of the cochlea. At the apex of the cochlea the lamina spiralis terminates by a pointed, hook-shaped process, the hamulus laminae spiralis. The two scalae of the cochlea, which are completely separated throughout their length in the living ear, communicate superiorly over the hamulus laminae spiralis by means of an opening common to both, which has been termed by Breschet helico-trema (ἡλικότρεμα) (ἱλιόσωννυμα). Inferiorly, one of the two scalae, the scala vestibuli, terminates by means of an oval aperture in the anterior ventricle of the vestibule; while the other, the scala tympani, becomes somewhat expanded, and opens into the tympanum through the fenestra rotunda (fenestra cochleae). Near the termination of the scala tympani is the small opening of the aqueductus cochleae.

The internal surface of the osseous labyrinth is lined by a fibro-serous membrane, which is analogous to the dura mater in performing the office of a periosteum by its exterior, whilst it fulfils the purpose of a serous membrane by its internal layer, secreting a limpid fluid, the aqua labyrinthis (liquor Cotunnii), and sending a reflection inwards upon the nerves distributed to the membranous labyrinth. In the cochlea the membrane of the labyrinth invests the two surfaces of the bony lamina spiralis, and being continued from its border across the diameter of the canal to its outer wall, forms the membranous lamina spiralis, and completes the separation between the scala tympani and scala vestibuli. The fenestra ovalis and fenestra rotunda are closed by an extension of this membrane across them, assisted by the membrane of the tympanum and a proper intermediate layer. Besides lining the interior of the osseous cavity, the membrane of the labyrinth sends two delicate processes along the aqueducts of the vestibule and cochlea to the internal surface of the dura mater, with which they are continuous. These processes are the remains of a communication
originally subsisting between the dura mater and the cavity of the labyrinth.†

The Membranous Labyrinth is smaller in size, but a perfect counterpart with respect to form, of the vestibule and semicircular canals. It consists of a small elongated sac, sacculus communis (utriculus communis); of three semicircular membranous canals, which correspond with the osseous canals, and communicate with the sacculus communis; and of a small round sac (sacculus proprius), which occupies the anterior ventricle of the vestibule, and lies in close contact with the external surface of the sacculus communis. The

* The labyrinth of the left ear, laid open in order to show its cavities and the membranous labyrinth. After Breschet. 1. The cavity of the vestibule, opened from its anterior aspect in order to show the three-cornered form of its interior, and the membranous labyrinth which it contains. The figure rests upon the common sacule of the membranous labyrinth,—the sacculus communis. 2. The ampulla of the superior or perpendicular semicircular canal, receiving a nervous fasciculus from the superior branch of the vestibular nerve, 3. 4. The superior or perpendicular canal with its contained membranous canal. 5. The ampulla of the inferior or horizontal semicircular canal, receiving a nervous fasciculus from the superior branch of the vestibular nerve. 6. The termination of the membranous canal of the horizontal semicircular canal in the sacculus communis. 7. The ampulla of the middle or oblique semicircular canal, receiving a nervous fasciculus from the inferior branch of the vestibular nerve. 8. The oblique semicircular canal with its membranous canal. 9. The common canal, resulting from the union of the perpendicular with the oblique semicircular canal. 10. The membranous common canal terminating in the sacculus communis. 11. The otoconite of the sacculus communis seen through the membranous parietes of that sac. A nervous fasciculus from the inferior branch of the vestibular nerve is seen to be distributed to the sacculus communis near the otoconite. The extremity of the sacculus above the otoconite is lodged in the superior ventricle of

† Cotunnius regarded these processes as tubular canals, through which the superabundant aqua labyrinthi might be expelled into the cavity of the cranium. Mr. Wharton Jones, in the article "Organ of Hearing," in the Cyclopaedia of Anatomy and Physiology, also describes them as tubular canals which terminate beneath the dura mater of the petrous bone in a small dilated pouch. In the ear of a man deaf and dumb from birth, he found the termination of the aqueduct of the vestibule of unusually large size in consequence of irregular development.
DISTRIBUTION OF THE AUDITORY NERVE.

membranous semicircular canals are two-thirds smaller in diameter than the osseous canals.

The membranous labyrinth is retained in its position by means of the numerous nervous filaments which are distributed to it from the openings in the inner wall of the vestibule, and is separated from the lining membrane of the labyrinth by the aqua labyrinthi. In structure it is composed of four layers: an external or serous layer, derived from the lining membrane of the labyrinth; a vascular layer, in which an abundance of minute vessels are distributed; a nervous layer, formed by the expansion of the filaments of the vestibular nerve and an internal and serous membrane, by which the limpid fluid which fills its interior is secreted. Some patches of pigment have been observed by Mr. Wharton Jones in the tissue of the membranous labyrinth of man. Among animals such spots are constant.

The membranous labyrinth is filled in its interior with a limpid fluid, first well described by Scarpa, and thence named liquor Scarpæ* (endolympth, vitreous humour of the ear), and contains two small calcareous masses called otoconites. The otoconites (οὖς, ὁρός κίνοις, the ear-dust), consist of an assemblage of minute, crystalline particles of carbonate and phosphate of lime, held together by animal substance, and probably retained in form by a reflection of the lining membrane of the membranous labyrinth. They are found suspended in the liquor Scarpæ; one in the sacculus communis, the other in the sacculus proprius, from that part of each sac with which the nerves are connected.

The Auditory Nerve divides into two branches at the bottom of the cul de sac of the meatus auditorius internus; a vestibular nerve, and a cochlear nerve. The vestibular nerve, the most posterior of the two, divides into three branches, superior, middle, and inferior. The superior vestibular branch gives off a number of filaments which pass through the minute openings of the eminentia pyramidalis and the vestibule, and that below it in the inferior ventricle. 12. The sacculus proprius situated in the anterior ventricle; its otoconite is seen through its membranous parietes, and a nervous fasciculus derived from the middle branch of the vestibular nerve is distributed to it. The spaces around the membranous labyrinth are occupied by the aqua labyrinthi. 13. The first turn of the cochlea; the figure points to the scala tympani. 14. The extremity of the scala tympani corresponding with the fenestra rotunda. 15. The lamina spiralis; the figure is situated in the scala vestibuli. 16. The opening of the scala vestibuli into the vestibule. 17. The second turn of the cochlea; the figure is placed upon the lamina spiralis, and therefore in the scala vestibuli, the scala tympani being beneath the lamina. 18. The remaining half turn of the cochlea; the figure is placed in the scala tympani. 19. The lamina spiralis terminating in a falciform extremity. The dark space included within the falciform curve of the extremity of the lamina spiralis is the helicotrema. 20. The infundibulum.

* Antonio Scarpa is celebrated for several beautiful surgical and anatomical monographs; as, for example, his work on "Aneurism," "De Auditu et Olfactu," &c. An account of the aqua labyrinthi will be found in his anatomical observations "De Structurâ Fenestræ Rotundæ, et de Tympano Secundario."
superior ventricle of the vestibule, and are distributed to the sacculus communis and ampullæ of the perpendicular and horizontal semicircular canals. The middle vestibular branch sends off numerous filaments, which pass through the openings of the macula cribrosa in the anterior ventricle of the vestibule, and are distributed to the sacculus proprius. The inferior and smallest branch takes its course backwards to the posterior wall of the vestibule, and gives off filaments which pierce the wall of the ampullary dilatation of the oblique canal to be distributed upon its ampulla. According to Stieffensand there is in the situation of the point of entrance of the nervous filaments into the ampullæ a deep depression upon the exterior of the membrane, and upon the interior a corresponding projection, which forms a kind of transverse septum, partially dividing the cavity of the ampulla into two chambers. In the substance of the sacculi and ampullæ, the nervous filaments radiate in all directions, anastomosing with each other, and forming interlacements and loops, and they terminate upon the inner surface of the membrane in minute papillæ, resembling those of the retina.

The Cochlear nerve divides into numerous filaments which enter the foraamina of the tractus spiralis foraminulentus in the base of the cochlea, and passing upwards in the canals of the modiolus, bend outwards at right angles, to be distributed in the tissue of the lamina spiralis. The central portion of the nerve passes through the tubulus centralis of the modiolus, and supplies the apical portion of the lamina spiralis. In the lamina spiralis the nervous filaments lying side by side on an even plane form numerous anastomosing loops, and spread out into a nervous membrane. According to Treviranus and Gottsch, the ultimate terminations of the filaments assume the form of papillæ.

The Arteries of the labyrinth are derived principally from the auditory branch of the superior cerebellar artery.

ORGAN OF TASTE.

The Tongue is composed of muscular fibres, which are distributed in layers arranged in various directions: thus, some are disposed longitudinally; others transversely; others, again, obliquely and vertically. Between the muscular fibres is a considerable quantity of adipose substance.

The tongue is connected posteriorly with the os hyoides by muscular attachment, and to the epiglottis by mucous membrane, forming the three folds which are called frâna epiglottidis. On either side it is held in connection with the lower jaw by mucous membrane, and in front a fold of that membrane is formed beneath its under surface, which is named frâmum linguae.

The surface of the tongue is covered by a dense layer analogous to the corium of the skin, which gives support to papillæ. A râphé
marks the middle line of the organ, and divides it into symmetrical halves.

The Papillæ of the tongue are the —

Papillæ circumvallatae,
Papillæ conicae,
Papillæ filiformes,
Papillæ fungiformes.

The Papillæ circumvallatae are of large size, and from fifteen to twenty in number. They are situated on the dorsum of the tongue, near its root, and form a row on each side, which meets its fellow at the middle line, like the two branches of the letter A. Each papilla resembles a cone, attached by its apex to the bottom of a cup-shaped depression; hence they are also named papillae calyceiformes. This cup-shaped cavity forms a kind of fossa around the papilla, whence their name circumvallata. At the meeting of the two rows of these papillæ upon the middle of the root of the tongue, is a deep mucous follicle called foramen caecum.

The Papillæ conicae and filiformes cover the whole surface of the tongue in front of the circumvallatae, but are most abundant near its apex. They are conical and filiform in shape, and have their points directed backwards.

The Papillæ fungiformes are irregularly dispersed over the dorsum of the tongue, and are easily recognised among the other papillæ by their rounded heads and larger size. A number of these papillæ will generally be observed at the tip of the tongue.

Behind the papillæ circumvallatae, at the root of the tongue, are a number of mucous glands, which open upon the surface. They have been improperly described as papillæ by some authors.

Vessels and Nerves.—The tongue is abundantly supplied with blood by the lingual arteries.

The Nerves are three in number, and of large size: The gustatory branch of the fifth, which is distributed to the papillæ, and is the nerve of common sensation and of taste. The glossopharyngeal, which is distributed to the mucous membrane, follicles, and glands of the tongue, is a nerve of sensation and motion; it also serves to associate the tongue with the pharynx and larynx. Panizza's experiments, tending to prove that this is the true nerve of taste, are rendered questionable by recent observations. The hypoglossal is the motor nerve of the tongue, and is distributed to the muscles.

The Mucous membrane which invests the tongue, is continuous with the dermis along the margin of the lips. On either side of the frænum linguae it may be traced through the sublingual ducts into the sublingual glands, and along Wharton's* ducts into the sub-

* Thomas Wharton, an English physician, devoted considerable attention to
maxillary glands: from the sides of the cheeks it passes through the openings of Stenon's* ducts to the parotid glands: in the fauces, it forms the assemblage of follicles called tonsils, and may be thence traced downwards into the larynx and pharynx, where it is continuous with the general gastro-pulmonary mucous membrane.

Beneath the mucous membrane of the mouth are a number of small glandular granules, which pour their secretion upon the surface. A considerable number of them are situated within the lips, in the palate, and in the floor of the mouth. They are named from the position which they may chance to occupy, labial, palatine glands, &c.

ORGAN OF TOUCH.

The Skin is the exterior investment of the body, which it serves to cover and protect. It is continuous at the apertures of the internal cavities with the lining membrane of those cavities, the internal skin or mucous membrane, and is composed essentially of two layers, dermis and epidermis.

The dermis or cutis is chiefly composed of areolar tissue, besides which it has entering into its structure elastic and contractile fibrous tissue, together with blood-vessels, lymphatic vessels and nerves. The areolar tissue exists in greatest abundance in the deeper stratum of the dermis, which is consequently dense, white, and coarse; the superficial stratum, on the other hand, is fine in texture, reddish in colour, soft, raised into minute papillæ, and highly vascular and sensitive. These differences in structure have given rise to a division of the dermis into the deep stratum, or corium, and the superficial, or papillary layer.

In the Corium the areolar tissue is collected into fasciculi, which are small, and closely interwoven in the superficial strata, large and coarse in the deep strata; in the latter forming an areolar network with large areolæ, which are occupied by adipose tissue. These areolæ are the channels by which the branches of vessels and nerves find a safe passage to the papillary layer, in which and in the superficial strata of the corium they are principally distributed. The yellow elastic tissue is found chiefly in the superficial strata, the red contractile tissue in the deep. It is to the latter that the nipples and scrotum owe their contractile powers, and the general surface of the skin the contraction which is known by the name of cutis anserina.

The corium presents some variety in thickness in different parts of the body. Thus in the more exposed regions, as the back, the outer sides of the limbs, the palms and the soles, it is remarkable for its thickness; while on protected parts it is comparatively thin. On the

the anatomy of the various glands: his work, intitled "Adenographia," &c. was published in 1656.

* Nicholas Stenon, a Danish anatomist: he was made professor in Copenhagen in 1672.
eyelids, the penis, and the scrotum it is peculiarly delicate. It is connected by its under surface with the common superficial fascia of the body.

The Papillary layer of the dermis is raised in the form of conical prominences or papillae. Upon the general surface of the body the papillae are short and exceedingly minute; but in other situations, as on the palmar surface of the hands and fingers, and on the plantar surface of the feet and toes, they are long and of large size. They also differ in arrangement; for on the general surface they are distributed at equal distances and without order; whereas on the palms and soles, and on the corresponding surfaces of the fingers and toes, they are collected into little square clumps containing from ten to twenty papillae; and these little clumps are disposed in parallel rows. It is this arrangement in rows that gives rise to the characteristic parallel ridges and furrows which are met with on the hands and feet. The papillae in these little square clumps are for the most part uniform in size and length, but every here and there one papilla may be observed which is longer than the rest. The largest papillae of the dermis are those which produce the nail; in the dermic follicle of the nail they are long and filiform, while beneath its concave surface they form longitudinal and parallel plications which extend for nearly the entire length of that organ. In structure each papilla is composed of a more or less convoluted capillary and a more or less convoluted nervous loop.

The Epidermis or cuticle (scarf-skin) is a product of the dermis,

* Anatomy of a portion of skin taken from the palm of the hand. 1, 1. The papillary layer, in which the longitudinal furrows (2) marking the arrangement of the papillae into ridges is shown. Each ridge is moreover divided by transverse furrows (3) into small quadrangular clumps. The quadrangular clumps consist of a tuft of minute conical papille, of which one or two are frequently longer and larger than the rest. In this figure the long papilie are alone seen, the rest being too numerous to introduce into a wood-engraving. 4. The rete mucosum raised from the papillary layer and turned back; the under surface of this stratum presents an accurate impression of the papillary layer; on which are seen longitudinal ridges corresponding with the longitudinal furrows, transverse ridges corresponding with the transverse furrows, and quadrangular depressions corresponding with the quadrangular clumps of papille. Moreover, wherever one of the long papille exists, a distinct conical sheath will be found in the rete mucosum. 5. 5. Perspiratory ducts drawn out straight by the separation of the rete mucosum from the papillary layer; the point at which each perspiratory duct issues from the papillary layer, and pierces the rete mucosum, is the middle of the transverse furrow between the quadrangular masses.
which it serves to envelope and defend. That surface of the epidermis which is exposed to the influence of the atmosphere and exterior sources of injury is hard and horny in texture, while that which lies in contact with the papillary layer is soft and cellular. Hence the epidermis, like the dermis, is divisible into two layers, external and internal, the latter being termed the rete mucosum. Moreover, the epidermis is laminated in structure, and the laminae present a progressively increasing tenuity and density as they advance from the inner to the outer surface. This difference of density is dependent on the mode of growth of the epidermis, for as the external surface is constantly subjected to destruction from attrition and chemical action, so the membrane is continually reproduced on its internal surface, new layers being successively formed on the dermis to take the place of the old.

The mode of growth of the epidermis may be thus briefly explained; a stratum of plastic lymph (liquor sanguinis) is poured out upon the surface of the dermis. This fluid, by virtue of the vital force inherent in itself, and communicated to it by contact with a living tissue, is converted into granules, which are termed cell-germs or cyto-blasts. By endosmosis, these cyto-blasts imbibe serum from the lymph and adjacent tissues, and the outermost layer or pellicle of the cyto-blast becomes gradually distended by the imbibed fluid. The cyto-blast has now become a cell, and the solid portion of the cyto-blast, which always remains adherent to some one point of the internal surface of the cell membrane, is the nucleus of the cell. Moreover, within the nucleus one or several nuclei are formed which are termed nucleoli. By a continuance of the process of imbibition, the cell becomes more or less spherical; so that, at this period, every part of the surface of the papillary layer of the dermis is coated by a thin and membranous stratum, consisting of spherical cells lying closely pressed together, and corresponding with every irregularity which the papillae present. But, as this production of cells is a function constantly in operation, a new layer is formed before the first is completed, and the latter is separated by subsequent formations farther and farther from the surface of the

* A diagram illustrative of the development of the epidermis, and of epithelia in general. 1. A granule or cyto-blast. 2. The cell seen rising on the cyto-blast; the latter is now a nucleus and a nucleolus may be detected in its interior. 3. The spheroidal cell. 4. The oval cell. 5. The elliptical cell. 6. The flattened cell; which, by contact of its walls, is speedily converted into a scale in which the nucleus is lost. 7. A nucleated scale as seen upon its flat surface. 8. A cluster of such scales.
papillary layer. With loss of contact with the dermis, the vital force is progressively diminished; the cell becomes subject to the influence of physical laws, and evaporation of its fluid slowly ensues. In consequence of this evaporation the cell becomes collapsed and flattened, and assumes an elliptical form; the latter is by degrees converted into the flat cell with parallel and contiguous layers, and an included nucleolated nucleus; and lastly, the flattened cell desiccates into a thin membranous scale, in which the nucleus is no longer apparent, and is thrown off by desquamation.

From this explanation it is apparent that the epidermis must be composed of a series of strata of nucleolo-nucleated cells, which exhibit a progressive increase of flattening, from the plastic fluid and cyto-blasts of the deepest layer to the thin and horny scales of the outermost layers. It is this peculiarity that enables us to split the epidermis into laminae, the deepest of these laminae, composed of the soft and newly formed cyto-blasts and cells, being the rete mucosum. In the deepest layer, the cyto-blasts are connected with each other by the unemployed portion of plastic lymph which constitutes an intercellular substance; the cells are connected by their parietes, and the flattened cells and scales by their surfaces and borders.

The under surface of the epidermis is accurately modelled on the papillary layer of the dermis, each papilla having its appropriate sheath in the newly-formed epidermis or rete mucosum, and each irregularity of surface of the former having its representative in the soft tissue of the latter. On the external surface, this character is lost; the minute elevations corresponding with the papillae, are, as it were, polished down, and the surface is rendered smooth and uniform. The palmar and plantar surfaces of the hands and feet are, however, an exception to this rule; for here, in consequence of the large size of the papillae and their peculiar arrangement in rows, ridges corresponding with the papillae are strongly marked on the superficial surface of the epidermis. The epidermis is remarkable for its thickness in situations where the papillae are large, as in the palms and soles. In other situations, it assumes a character which is also due to the nature of the surface of the dermis; namely, that of being marked by a network of linear furrows, which trace out the surface into small polygonal and lozenge-shaped areas. These lines correspond with the folds of the dermis produced by its movements, and are most numerous where those movements are the greatest, as in the plexuses and on the convexities of joints.

The dark colour of the skin among the natives of the South is due to the presence of granules of pigment, which are disseminated in the interstices of the cyto-blasts and cells of the rete mucosum, or developed in the same situation into proper pigment cells. In the superficial layers of the epidermis, as evaporation proceeds, the colour of the pigment is gradually lost.

The pores of the epidermis are the openings of the perspiratory ducts, hair follicles, and sebaceous follicles.
Vessels and Nerves.—The Arteries of the dermis which enter its structure through the areolae of the under surface of the corium, divide into innumerable intermediate vessels, which form a rich capillary plexus in the superficial strata of the skin and in its papillary layer. In the papillae of some parts of the dermis, as in the longitudinal plications beneath the nail, the capillary vessels form simple loops, but in other papillae they are convoluted to a greater or less degree in proportion to the size and importance of the papillae. The Lymphatic vessels probably form, in the superficial strata of the dermis, a plexus, the meshes of which are interwoven with those of the capillary and nervous plexus. No lymphatics have as yet been discovered in the papillae.

The Nerves of the dermis, after entering the areolae of the deeper part of the corium, divide into minute fasciculi, and these quickly separate into primitive fibres, which form loops in the papillae. In the less sensitive parts of the skin the loops are simple, and more or less acute in their bend, in conformity with the figure of the papilla. In the sensitive parts, however, and especially in the tactile papillae of the pulps of the fingers, the loop is convoluted to a greater or less extent, and acts as a multiplier of sensation.

APPENDAGES OF THE SKIN.

The appendages of the skin are the nails, hairs, sebaceous glands, and perspiratory glands and ducts.

The Nails are horny appendages of the skin, identical in formation with the epidermis, of which they are a part. A nail is convex on its external surface, concave within, and implanted by means of a thin margin or root in a fold of the dermis (matrix), which is nearly two lines in depth, and acts the part of a follicle to the nail. At the bottom of the groove of the follicle are a number of filiform papillae, which produce the margin of the root, and, by the successive formation of new cells, push the nail onwards in its growth. The concave surface of the nail is in contact with the dermis, and the latter is covered by papillae, which perform the double office of retaining the nail in its place, and giving it increased thickness by the addition of newly-formed cells to its under surface. It is this constant change occurring in the under surface of the nail, co-operating with the continual re-production taking place along the margin of the root, which ensures the growth of the nail in the proper direction. The nail derives a peculiarity of appearance from the disposition and form of the papillae on the unguinal surface of the dermis. Thus, beneath the root, and for a short distance onwards towards its middle, the dermis is covered by papillae which are more minute, and consequently less vascular than the papillae somewhat farther on. This patch of papillae is bounded by a semilunar line, and that part of the nail covering it being lighter in colour than the rest, has been termed lunula. Beyond the lunula the papillae are raised into longitudinal plaits, which are exceedingly vascu-
lar, and give a deeper tint of redness to the nail. These plait-like papillae of the dermis are well calculated by their form to offer an extensive surface both for the adhesion and formation of the nail. The cyto-blasts and cells are developed on every part of their surface, both in the grooves between the plaits and on their sides, and a lamina of nail is formed between each pair of plaits. When the under surface of a nail is examined, these longitudinal laminae, corresponding with the longitudinal papille of the ungual portion of the dermis, are distinctly apparent, and if the nail be forcibly detached, the laminae may be seen in the act of parting from the grooves of the papille. It is this structure that gives rise to the ribbed appearance of the nail. The papillary surface of the dermis which produces the nail is continuous around the circumference of the attached part of that organ with the dermis of the surrounding skin, and the horny structure of the nail is consequently continuous with that of the epidermis.

Hairs are horny appendages of the skin produced by the involution and subsequent evolution of the epidermis; the involution constituting the follicle in which the hair is enclosed, and the evolution the shaft of the hair. Hairs vary much in size and length in different parts of the body; in some they are so short as not to appear beyond the follicle; in others they grow to a great length, as on the scalp; while along the margins of the eyelids and in the whiskers and beard, they are remarkable for their thickness. Hairs are generally more or less flattened in form, and when the extremity of a transverse section is examined, it is found to possess an elliptical or reniform outline. This examination also demonstrates that the centre of the hair is porous and loose in texture, while its circumference is dense; thus affording some ground for a division into a cortical and a medullary portion. The free extremity of a hair is generally pointed, and sometimes split into two or three filaments. Its attached extremity is implanted deeply in the integument extending through the dermis into the sub-cutaneous areolar tissue, where it is surrounded by adipose cells. The central extremity of a hair is larger than its shaft, and is called the root or bulb. It is usually infundibular in form in the larger hairs, and conical in the smaller hairs, and those of the head.

At the bottom of each hair-follicle is a vascular and sensitive formative substance or pulp, which is analogous to a papilla of the dermis, and is the producing organ of the hair. The process of formation of a hair by its pulp is identical with that of the formation of the epidermis by the papillary layer of the dermis. A stratum of plastic lymph is in the first instance exuded by the capillary plexus of the pulp, the lymph undergoes conversion, first into cyto-blasts, then into cells, and the latter are either lengthened out or split into fibres. The cells which are destined to form the surface of the hair undergo a different process. They are converted into flat scales, which enclose the fibrous structure of the interior. These scales, as they are successively produced, overlap those which precede and give rise to the prominent and waving lines which may be seen around the circumference of a hair.
It is this overlapping line that is the cause of the roughness which we experience in drawing a hair from its point to its bulb between the fingers. The bulb is the newly formed portion of the hair: it corresponds in figure with that of the pulp, and its expanded form is due to the greater bulk of the fresh cells as compared with the fibres and scales into which they are subsequently converted in the shaft of the hair.

The colour of the hair, like that of the epidermis, is due to the presence of granules of pigment contained within and among the cells.

The Sebaceous glands are sacculated glandular organs embedded in the substance of the dermis, and presenting every variety of complexity, from the simplest pouch-like follicle to the sacculated and lo-

* The anatomy of the skin. 1. The epidermis, showing the oblique laminae of which it is composed, and the imbricated disposition of the ridges upon its surface. 2. The rete mucosum or deep layer of the epidermis. 3. Two of the quadrilateral papillary clumps, such as are seen in the palm of the hand or sole of the foot; they are composed of minute conical papille. 4. The deep layer of the cutis, the corium. 5. Another sudoriparous gland with a straighter duct, such as is seen in the scalp. 8. Two hairs from the scalp, enclosed in their follicles; their relative depth in the skin is preserved. 9. A pair of sebaceous glands, opening by short ducts into the follicle of the hair.
bulated gland. In some situations, the excretory ducts of these glands open independently on the surface of the epidermis; while in others, and the most numerous, they terminate in the follicles of the hairs. The sebaceous glands associated with the hairs are racemiform and lobulated in structure, consisting of saeculi which open by short pedunculated tubuli into a common excretory duct, and the latter, after a short course, terminates in the hair-follicle. In the scalp there are two of these glands to each hair-follicle. On the nose and face the glands are of large size, distinctly lobulated, and constantly associated with small hair-follicles. In the meatus auditorius the sebaceous (ceruminous) glands are also large and lobulated, but the largest are those of the eyelids, the Meibomian glands. The excretory ducts of sebaceous glands offer some diversity in different parts of the body: thus in many situations they are short and straight, while in others, as in the palms of the hands and soles of the feet, where the epidermis is thick, they assume a spiral arrangement. The sebaceous ducts and glands are lined by an inversion of the epidermis, which forms a thick and funnel-shaped cone at its commencement, but soon becomes uniform and soft. Sebaceous glands are met with in all parts of the body, but are most abundant in the skin of the face, and in those situations which are naturally exposed to the influence of friction.

The sebaceous substance when it collects in inordinate quantities within the excretory ducts becomes the habitat of a very remarkable parasitic animal, the entozoon folliculorum.

The SUDORIPAROUS GLANDS are situated deeply in the integument, namely, in the subcutaneous areolar tissue, where they are surrounded by adipose cells. They are small, oblong bodies, composed of one or more convoluted tubuli, or of a congeries of globular sacs, which open into a common efferent duct. The latter ascends from the gland through the dermis and epidermis, and terminates on the surface by a funnel-shaped and oblique aperture or pore. The efferent duct presents some variety in its course upwards: thus, below the dermis it is curved and serpentine, and having pierced the dermis, if the epidermis be thin, it proceeds more or less directly to the excreting pore. Sometimes it is spirally curved beneath the dermis, and having passed the latter, is regularly and beautifully spiral in its passage through the epidermis, the last turn forming an oblique and valvular opening on the surface. The spiral course of the duct is especially remarkable in the thick epidermis of the palm of the hand and sole of the foot. On those parts of the skin where the papillae are irregularly distributed, the efferent ducts of the sudoriparous glands open on the surface also irregularly, while on the palmar and plantar surfaces of the hands and feet, the pores are situated at regular distances along the ridges, at points corresponding with the intervals of the small, square-shaped clumps of papillae. Indeed the apertures of the pores, seen upon the surface of the epidermic ridges, give rise to the appearance of small transverse furrows, which intersect the ridges from point to point.

The efferent duct and the component sacs and tubuli of the sudori-
parous gland are lined by an inflection of the epidermis. This inflection is thick and infundibiliform in the upper stratum of the dermis, but soon becomes uniform and soft. The infundibiliform projection is drawn out from the duct when the epidermis is removed, and may be perceived on the under surface of the latter as a nipple-shaped cone. A good view of the sudoriferous ducts is obtained by gently separating the epidermis of a portion of decomposing skin; or they may be better seen by scalding a piece of skin, and then withdrawing the epidermis from the dermis. In both cases it is the lining sheath of epidermis which is drawn out from the duct.
CHAPTER X.

OF THE VISCERA.

That part of the science of anatomy which treats of the viscera is named splanchnology, from the Greek words σφάλγχλος, viscus, and λόγος. The viscera of the human body are situated in the three great internal cavities: cranio-spinal, thorax, and abdomen. The viscera of the cranio-spinal cavity, namely, the brain and spinal cord, with the principal organs of sense, have been already described, in conjunction with the nervous system. The viscera of the chest are: the central organ of circulation, the heart; the organs of respiration, the lungs; and the thymus gland. The abdominal viscera admit of a subdivision into those which properly belong to that cavity, viz. the alimentary canal, liver, pancreas, spleen, kidneys, and supra-renal capsules, and those of the pelvis: the bladder and internal organs of generation.

THORAX.

The thorax is the conical cavity, situated at the upper part of the trunk of the body; it is narrow above and broad below, and is bounded by the sternum, six superior costal cartilages, ribs, and intercostal muscles in front; laterally, by the ribs and intercostal muscles; and, behind, by the same structures, and by the vertebral column, as low down as the upper border of the last rib and the first lumbar vertebra; superiorly, by the thoracic fascia and first ribs; and inferiorly, by the diaphragm. This cavity is much deeper on the posterior than on the anterior wall, in consequence of the obliquity of the diaphragm, and contains the heart enclosed in its pericardium, with the great vessels; the lungs, with their serous coverings, the pleura; the oesophagus; some important nerves; and, in the foetus, the thymus gland.

THE HEART.

The central organ of circulation, the heart, is situated between the two layers of pleura which constitute the mediastinum, and is enclosed in a proper membrane, the pericardium.

Pericardium.—The pericardium is a fibro-serous membrane like the dura mater, and resembles that membrane in deriving its serous layer from the reflected serous membrane of the viscus which it encloses.
It consists, therefore, of two layers, an external fibrous and an internal serous. The fibrous layer is attached, above, to the great vessels at the root of the heart, where it is continuous with the thoracic fascia; and below, to the tendinous portion of the diaphragm. The serous membrane invests the heart with the commencement of its great vessels, and is then reflected upon the internal surface of the fibrous layer.

The Heart is placed obliquely in the chest, the base being directed upwards and backwards towards the right shoulder; the apex forwards and to the left, pointing to the space between the fifth and sixth ribs, at about two or three inches from the sternum. Its under side is flattened, and rests upon the tendinous portion of the diaphragm; its upper side is rounded and convex, and formed principally by the right ventricle, and partly by the left. Surmounting the ventricles are the corresponding auricles, whose auricular appendages are directed forwards, and slightly overlap the root of the pulmonary artery. The pulmonary artery is the large anterior vessel at the root of the heart; it crosses obliquely the commencement of the aorta. The heart consists of two auricles and two ventricles, which are respectively named, from their position, right and left. The right is the venous side of the heart; it receives into its auricle the venous blood from every part of the body, by the superior and inferior cava and coronary vein. From the auricle the blood passes into the ventricle, and from the ventricle through the pulmonary artery, to the capillaries of the lungs. From these it is returned as arterial blood to the left auricle; from the left auricle it passes into the left ventricle; and from the left ventricle is carried through the aorta, to be distributed to every part of the body, and again returned to the heart by the veins. This constitutes the course of the adult circulation.

The heart is best studied in situ. If, however, it be removed from the body, it should be placed in the position indicated in the above description of its situation. A transverse incision should then be made along the ventricular margin of the right auricle, from the appendix to its right border, and crossed by a perpendicular incision, carried from the side of the superior to the inferior cava. The blood must then be removed. Some fine specimens of white fibrin are frequently found with the coagula; occasionally they are yellow and gelatinous. This appearance deceived the older anatomists, who called these substances "polypus of the heart;" they are also frequently found in the right ventricle, and sometimes in the left cavities.

The Right Auricle is larger than the left, and is divided into a principal cavity or sinus, and an appendix auriculæ. The interior of the sinus presents for examination five openings; two valves; two relics of foetal structure; and two peculiarities in the proper structure of the auricle. They may be thus arranged:—
The anatomy of the heart. 1. The right auricle. 2. The entrance of the superior vena cava. 3. The entrance of the inferior cava. 4. The opening of the coronary vein, half closed by the coronary valve. 5. The Eustachian valve. 6. The fossa ovalis, surrounded by the annulus ovalis. 7. The tuberculum Laveri. 8. The musculi pectinati in the appendix auriculæ. 9. The auriculo-ventricular opening. 10. The cavity of the right ventricle. 11. The tricuspid valve, attached by the chordæ tendineæ to the carnae columnæ (12). 13. The pulmonary artery, guarded at its commencement by three semilunar valves. 14. The right pulmonary artery, passing beneath the arch and behind the ascending aorta. 15. The left pulmonary artery, crossing in front of the descending aorta. * The remains of the ductus arteriosus, acting as a ligament between the pulmonary artery and arch of the aorta. The arrows mark the course of the venous blood through the right side of the heart. Entering the auricle by the superior and inferior cavae, it passes through the auriculo-ventricular opening into the ventricle, and thence through the pulmonary artery to the lungs. 16. The left auricle. 17. The openings of the four pulmonary veins. 18. The auriculo-ventricular opening. 19. The left ventricle. 20. The mitral valve, attached by its chordæ tendineæ to two large columnæ carnae, which project from the walls of the ventricle. 21. The commencement and course of the ascending aorta behind the pulmonary artery, marked by an arrow. The entrance of the vessel is guarded by three semilunar valves. 22. The arch of the aorta. The comparative thickness of the two ventricles is shown in the diagram. The course of the pure blood through the left side of the heart is marked by arrows. The blood is brought from the lungs by the four pulmonary veins into the left auricle, and passes through the auriculo-ventricular opening into the left ventricle, whence it is conveyed by the aorta to every part of the body.
The **Superior cava** returns the blood from the upper half of the body, and opens into the upper and front part of the auricle.

The **Inferior cava** returns the blood from the lower half of the body, and opens through the lower and posterior wall, close to the partition between the auricles (septum auricularum). The direction of these two vessels is such, that a stream forced through the superior cava would be directed towards the auriculo-ventricular opening. In like manner, a stream rushing upwards by the inferior cava would force its current against the septum auricularum; this is the proper direction of the two currents during fetal life.

The **Coronary vein** returns the venous blood from the substance of the heart; it opens into the auricle between the inferior cava and the auriculo-ventricular opening, under cover of the coronary valve.

The **Foramina Thebesii** are minute pore-like openings, by which the venous blood exudes directly from the muscular structure of the heart into the auricle, without entering the venous current. These openings are also found in the left auricle, and in the right and left ventricles.

The **Auriculo-ventricular opening** is the large opening of communication between the auricle and ventricle.

The **Eustachian** valve is a part of the apparatus of fetal circulation, and serves to direct the placental blood from the inferior cava, through the foramen ovale into the left auricle. In the adult it is a mere vestige and imperfect, though sometimes it remains of large size. It is formed by a fold of the lining membrane of the auricle, containing some muscular fibres, is situated between the opening of the inferior cava and the auriculo-ventricular opening, and is generally connected with the coronary valve.

The **Coronary valve** is a semilunar fold of the lining membrane, stretching across the mouth of the coronary vein, and preventing the reflux of the blood in the vein during the contraction of the auricle.

The **Annulus ovalis** is situated on the septum auricularum, opposite the termination of the inferior cava. It is the rounded margin of the septum, which occupies the place of the foramen ovale of the foetus.

* Adam Christian Thebesius. His discovery of the openings now known by his name is contained in his "Dissertatio Medica de Circulo Sanguinis in Corde," 1708.
* Bartholomew Eustachius, born at San Severino, in Naples, was Professor of Medicine in Rome, where he died in 1570. He was one of the founders of modern anatomy, and the first who illustrated his works with good engravings on copper.
The *Fossa ovalis* is an oval depression corresponding with the foramen ovale in the foetus. This opening is closed at birth by a thin valvular layer, which is continuous with the left margin of the anulus and is frequently imperfect at its upper part. The depression or fossa in the right auricle results from this arrangement. There is no fossa ovalis in the left auricle.

The *Tuberculum Loweri* is the portion of auricle intervening between the openings of the superior and inferior cava. Being thicker than the walls of the veins it forms a projection, which was supposed by Lower to direct the blood from the superior cava into the auriculo-ventricular opening.

The *Musculi pectinati* are small muscular columns situated in the appendix auriculæ. They are numerous, and are arranged parallel with each other; hence their cognomen, "pectinati," like the teeth of a comb.

The *Right Ventricle* is triangular and prismoid in form. Its anterior side is convex, and forms the larger proportion of the front of the heart. The posterior side, which is also inferior, is flat, and rests upon the diaphragm; the inner side corresponds with the partition between the two ventricles, septum ventriculorum.

The right ventricle is to be laid open by making an incision parallel with, and a little to the right of, the middle line, from the pulmonary artery in front, to the apex of the heart, and thence by the side of the middle line behind to the auriculo-ventricular opening.

It contains, to be examined, two openings, the auriculo-ventricular and that of the pulmonary artery; two apparatus of valves, the tricuspid and semilunar; and a muscular and tendinous apparatus belonging to the tricuspid valves. They may be thus arranged:

- **Auriculo-ventricular opening**,  
  Opening of the pulmonary artery.
- **Tricuspid valves**,  
  Semilunar valves.
- **Chordæ tendineæ**,  
  Carnæ columnæ.

The *Auriculo-ventricular opening* is surrounded by a fibrous ring, covered by the lining membrane of the heart. It is the opening of communication between the right auricle and ventricle.

The *Opening of the pulmonary artery* is situated close to the septum ventriculorum, on the left side of the right ventricle, and upon the anterior aspect of the heart.

The *Tricuspid valves* are three triangular folds of the lining mem-

* Richard Lower, M.D. "Tractatus de Corde; item de Motu et Colore Sanguinis," 1669. His dissections were made upon quadrupeds, and his observations relate rather to animals than to man.
brane, strengthened by a thin layer of fibrous tissue. They are connected by their base around the auriculo-ventricular opening; and by their sides and apices, which are thickened, they give attachment to a number of slender tendinous cords, called chordae tendineae. The chordae tendineae are the tendons of the thick muscular columns (columnæ carneaæ) which stand out from the walls of the ventricle, and serve as muscles to the valves. A number of these tendinous cords converge to a single muscular attachment. The tricuspid valves prevent the regurgitation of blood into the auricle during the contraction of the ventricle, and they are prevented from being themselves driven back by the chordae tendineae and their muscular attachments.

This connection of the muscular columns of the heart to the valves has caused their division into active and passive. The active valves are the tricuspid and mitral; the passive, the semilunar and coronary.

Mr. King, of Guy's Hospital, has made the tricuspid valves the subject of careful investigation, and has recorded his observations in the Guy's Hospital Reports.* The valves consist, according to Mr. King, of curtains, cords, and columns. The anterior valve or curtain is the largest, and is so placed as to prevent the filling of the pulmonary artery during the distension of the ventricle. The right valve or curtain is of smaller size, and is situated upon the right side of the auriculo-ventricular opening. The third valve, or "fixed curtain," is connected by its cords to the septum ventriculorum. The cords (chordæ tendineæ) of the anterior curtain are attached, principally, to a long column (columna carnea), which is connected with the "right or thin and yielding wall of the ventricle." From the lower part of this column a transverse muscular band, the "long moderator band," is stretched to the septum ventriculorum or "solid wall" of the ventricle. The right curtain is connected, by means of its cords, partly with the long column, and partly with its own proper column, the second column, which is also attached to the "yielding wall" of the ventricle. A third and smaller column is generally connected with the right curtain. The "fixed curtain" is named from its attachment to the "solid wall" of the ventricle, by means of cords only, without fleshy columns.

From this arrangement of the valves it follows, that if the right ventricle be over-distended, the thin or "yielding wall" will give way, and carry with it the columns of the anterior and right valves. The cords connected with these columns will draw down the edges of the corresponding valves, and produce an opening between the curtains, through which the superabundant blood may escape into the auricle, and the ventricle be relieved from over-pressure. This beautiful mechanism is therefore adapted to fulfil the "function of a safety valve."

The Columnæ carneaæ (fleshy columns) is a name expressive of the appearance of the internal walls of the ventricles, which seem formed

of muscular columns interlacing in almost every direction. They are divided into three sets, according to the manner of their connection. 1. The greater number are attached by the whole of one side, and merely form convexities into the cavity of the ventricle. 2. Others are connected by both extremities, being free in the middle. 3. A few (columnæ papillares) are attached by one extremity to the walls of the heart, and by the other give insertion to the chordæ tendineæ.

The Semilunar valves, three in number, are situated around the commencement of the pulmonary artery, being formed by a folding of its lining membrane, strengthened by a thin layer of fibrous tissue. They are attached by their convex borders, and free by the concave which are directed upwards in the course of the vessel, so that, during the current of the blood along the artery they are pressed against the sides of the cylinder; but if any attempt at regurgitation ensue they are immediately expanded, and effectually close the entrance of the tube. The margins of the valves are thicker than the rest of their extent, and each valve presents in the centre of this margin a small fibro-cartilaginous tubercle, called corpus Arantii,* which locks in with the two others during the closure of the valves, and secures the triangular space that would otherwise be left by the approximation of three semilunar folds.

Between the semilunar valves and the cylinder of the artery are three pouches, called the pulmonary sinuses (sinuses of Valsalva). Similar sinuses are situated behind the valves at the commencement of the aorta, and are larger and more capacious than those of the pulmonary artery.

The Pulmonary artery commences by a scalloped border, corresponding with the three valves which are attached along its edge. It is connected to the ventricle by muscular fibres, and by the lining membrane of the heart.

The Left auricle is somewhat smaller, but thicker, than the right; of a cuboid form, and situated more posteriorly. The appendix auriculæ is constricted at its junction with the auricle, and has a foliated appearance; it is directed forwards towards the root of the pulmonary artery, to which the auriculæ of both sides appear to converge.

The left auricle is to be laid open by a + shaped incision, the horizontal section being made along the border which is attached to the base of the ventricle. It presents for examination five openings, and the muscular structure of the appendix; these are,—

Four pulmonary veins,
Auriculo-ventricular opening,
Musculi pectinati.

* Julius Cæsar Arantius, Professor of Medicine in Bologna. He was a disciple of Vesalius, one of the founders of modern anatomy. His treatise "De Humano Foetu" was published at Rome, in 1564.
The *Pulmonary veins*, two from the right and two from the left lung, open into the corresponding sides of the auricle. The two left pulmonary veins terminate frequently by a common opening.

The *Auriculo-ventricular opening* is the aperture of communication between the auricle and ventricle.

The *Musculi pectinati* are fewer in number than in the right auricle, and are situated only in the appendix auriculæ.

**LEFT VENTRICLE.**—The left ventricle is to be opened by making an incision a little to the left of the septum ventriculorum, and continuing it around the apex of the heart to the auriculo-ventricular opening behind.

The left ventricle is conical, both in external figure and in the form of its internal cavity. It forms the apex of the heart, by projecting beyond the right ventricle, while the latter has the advantage in length towards the base. Its walls are about seven lines in thickness, those of the right ventricle being about two lines and a half.

It presents for examination, in its interior, two openings, two valves, and the tendinous cords and muscular columns; they may be thus arranged:

Auriculo-ventricular opening,
Aortic opening.
Mitral valves,
Semilunar valves.
Chordæ tendineæ,
Columnæ carneaæ.

The *Auriculo-ventricular opening* is a dense fibrous ring, covered by the lining membrane of the heart, but smaller in size than that of the right side.

The *Mitral valves* are attached around the auriculo-ventricular opening, as are the tricuspid in the right ventricle. They are thicker than the tricuspid, and consist of only two segments, of which the larger is placed between the auriculo-ventricular opening and the commencement of the aorta, and acts the part of a valve to that foramen during the filling of the ventricle. The difference in size of the two valves, both being triangular, and the space between them, has given rise to the idea of a "bishop’s mitre," after which they were named. These valves, like the tricuspid, are furnished with an apparatus of tendinous cords, chordæ tendineæ, which are attached to two very large columnæ carneaæ.

The *Columnæ carneaæ* admit of the same arrangement into three kinds, as on the right side. Those which are free by one extremity, the columnæ papillares, are two in number, and larger than those on the opposite side; one being placed on the left wall of the ventricle, and the other at the junction of the septum ventriculorum with the posterior wall.
The *Semilunar valves* are placed around the commencement of the aorta, like those of the pulmonary artery; they are similar in structure, and are attached to the scalloped border by which the aorta is connected with the ventricle. The tubercle in the centre of each fold is larger than those in the pulmonary valves, and it was these that Arantius particularly described; but the term "*corpora Arantii*" is now applied indiscriminately to both. The fossæ between the semilunar valves and the cylinder of the artery are larger than those of the pulmonary artery; they are called the "*sinus aortici*" (sinuses of Valsalva).

**STRUCTURE OF THE HEART.**

The arrangement of the fibres of the heart has been made the subject of careful and accurate investigation by Mr. Searle, to whose excellent article, "Fibres of the Heart," in the Cyclopaedia of Anatomy and Physiology, I am indebted for the following summary of their distribution:

For the sake of clearness of description the fibres of the ventricles have been divided into three layers, superficial, middle, and internal, all of which are disposed in a spiral direction around the cavities of the ventricles. The mode of formation of these three layers will be best understood by adopting the plan pursued by Mr. Searle in tracing the course of the fibres from the centre of the heart towards its periphery.

The left surface of the septum ventriculorum is formed by a broad and thick layer of fibres, which proceed backwards in a spiral direction around the posterior aspect of the left ventricle, and become augmented on the left side of that ventricle by other fibres derived from the bases of the two columnæ papillares. The broad and thick band formed by the fibres from these two sources, curves around the apex and lower third of the left ventricle to the anterior border of the septum, where it divides into two bands, a short or apical band, and a long or basal band.

The *Short* or *apical band* is increased in thickness at this point by receiving a layer of fibres (derived from the root of the aorta and carnae columnæ) upon its internal surface, from the right surface of the septum ventriculorum; it is then continued onwards in a spiral direction from left to right, around the lower third of the anterior surface, and the middle third of the posterior surface of the right ventricle to the posterior border of the septum. From the latter point the short band is prolonged around the posterior and outer border of the left ventricle to the anterior surface of the base of that ventricle, and is inserted into the anterior border of the left auriculo-ventricular ring, and the anterior part of the root of the aorta and pulmonary artery.

The *Long* or *basial band*, at the anterior border of the septum, passes
directly backwards through the septum, forming its middle layer, to
the posterior ventricular groove, where it becomes joined by fibres
derived from the root of the pulmonary artery. It then winds spirally
around the middle and upper third of the left ventricle to the anterior
border of the septum, where it is connected by means of its internal
surface with the superior fibres derived from the aorta, which form
part of the right wall of the septum. From this point it is continued
around the upper third of the anterior and posterior surface of the
right ventricle to the posterior border of the septum, where it is con-
ected with the fibres constituting the right surface of the septum
ventriculorum. At the latter point the fibres of this band begin to be
twisted upon themselves, like the strands of a rope, the direction of
the twist being from below upwards. This arrangement of fibres is
called by Mr. Searle "the rope;" it is continued spirally upwards,
forming the brim of the left ventricle, to the anterior surface of the
base of that ventricle, where the twisting of the fibres ceases. The
long band then curves inwards towards the septum, and spreads out
upon the left surface of the septum into the broad and thick layer of
fibres with which this description commenced.

The most inferior of the fibres of the left surface of the septum
ventriculorum, after winding spirally around the internal surface of the
apex of the left ventricle, so as to close its extremity, form a small
fasciculus, which is excluded from the interior of the ventricle, and
expands in a radiated manner over the surface of the heart, con-
stituting its superficial layer of fibres. The direction of these fibres is,
for the most part, oblique, passing from left to right on the anterior,
and from right to left on the posterior surface of the heart, becoming
more longitudinal near its base, and terminating by being inserted into
the fibrous rings of the auriculo-ventricular openings, and of the pul-
monary artery and aorta. Over the right ventricle the superficial
fibres are increased in number by the addition of accessory fibres from
the right surface of the septum, which pierce the middle layer, and
take the same direction with the superficial fibres from the apex of the
left ventricle, and of other accessory fibres from the surface of both
ventricles.

From this description it will be perceived, that the superficial layer
of fibres is very scanty, and is pretty equally distributed over the
surface of both ventricles. The middle layer of both ventricles is
formed by the two bands, short and long. But the internal layer of
the two ventricles is very differently constituted: that of the left is
formed by the spiral expansion of the fibres of the rope, and of the two
columnæ papillares; that of the right remains to be described. The
septum ventriculorum also consists of three layers, a left layer, the
radiated expansion of the rope and carnea columnæ; a middle layer,
the long band; and a right layer, belonging to the proper wall of the
right ventricle, and continuous both in front and behind with the long
band, and in front also with the short band, and with the superficial
layer of the right ventricle.
The Internal layer of the right ventricle is formed by fasciculi of fibres which arise from the right segment of the root of the aorta, from the entire circumference of the root of the pulmonary artery, and from the bases of the columnæ papillares. The fibres from the root of the aorta, associated with some from the carinæ columnæ, constitute a layer which passes obliquely forwards upon the right side of the septum. The superior fibres coming directly from the aorta join the internal surface of the long band at the anterior border of the septum, while the lower two-thirds of the layer are continuous with the internal surface of the short band, some of its fibres piercing that band to augment the number of superficial fibres. The fibres derived from the root of the pulmonary artery, conjoined with those from the base of one of the columnæ papillares, curve forwards from their origin, and wind obliquely downwards and backwards around the internal surface of the wall of the ventricle to the posterior border of the septum, where they become continuous with the long band, directly that it has passed backwards through the septum.

Fibres of the Auricles.—The fibres of the auricles are disposed in two layers, external and internal. The internal layer is formed of fasciculi which arise from the fibrous rings of the auriculo-ventricular openings and proceed upwards to enlace with each other, and constitute the appendices auricularem. These fasciculi are parallel in their arrangement, and in the appendices form projections and give rise to the appearance which is denominated musculi pectinati. In their course they give off branches which connect adjoining fasciculi, and form a columnar interlacement between them.

External Layer.—The fibres of the right auricle having completed the appendix, wind from left to right around the right border of this auricle, and along its anterior aspect, beneath the appendix, to the anterior surface of the septum. From the septum they are continued to the anterior surface of the left auricle, where they separate into three bands, superior, anterior, and posterior. The superior band proceeds onwards to the appendix, and encircles the apex of the auricle. The anterior band passes to the left, beneath the appendix, and winds as a broad layer completely around the base of the auricle, and through the septum to the root of the aorta, to which it is partly attached, and from this point is continued onwards to the appendix, where its fibres terminate by interlacing with the musculi pectinati. The posterior band crosses the left auricle obliquely to its posterior part, and winds from left to right around its base, encircling the openings of the pulmonary veins; some of its fibres are lost upon the surface of the auricle, others are continued onwards to the base of the aorta; and a third set, forming a small band, is prolonged along the anterior edge of the appendix to its apex, where it is continuous with the superior band. The septum auricularum has four sets of fibres entering into its formation; 1. The fibres arising from the auriculo-ventricular rings at each side; 2. Fibres arising from the root of the aorta, which pass upwards to the transverse band, and to the root of
the superior cava; 3. Those fibres of the anterior band that pass through the lower part of the septum in their course around the left auricle; and, 4. A slender fasciculus, which crosses through the septum from the posterior part of the right auriculo-ventricular ring to the left auricle.

It will be remarked from this description, that the left auricle is considerably thicker and more muscular than the right.

Vessels and Nerves.—The Arteries supplying the heart are the anterior and posterior coronary. The Veins accompany the arteries, and empty themselves by the common coronary vein into the right auricle. The lymphatics terminate in the glands about the root of the heart. The nerves of the heart are derived from the cardiac plexuses, which are formed by communicating filaments from the sympathetic and pneumogastric.

ORGANS OF RESPIRATION AND VOICE.

The organs of respiration are the two lungs, with their air-tube, the trachea, to the upper part of which is adapted an apparatus of cartilages, constituting the organ of voice, or larynx.

THE LARYNX.

The Larynx is situated at the fore part of the neck, between the trachea and the base of the tongue. It is a short tube, having an hour-glass form, and is composed of cartilages, ligaments, muscles, vessels, nerves, and mucous membrane.

The Cartilages are the—

Thyroid,
Cricoid,
Two Arytenoid,
Two cuneiform,
Epiglottis.

The Thyroid (Ὧψεῖς—sīdoś, like a shield) is the largest cartilage of the larynx: it consists of two lateral portions, or alae, which meet at an angle in front, and form the projection which is known by the name of pomum Adami. In the male after puberty the angle of union of the two alæ is acute; in the female, and before puberty in the male, it is obtuse. Where the pomum Adami is prominent, a bursa mucosa is often found between it and the skin.

Each ala is quadrilateral in shape, and forms a rounded border posteriorly, which terminates above, in the superior cornu, and below, in the inferior cornu. Upon the side of the ala is an oblique line, or ridge, directed downwards and forwards, and bounded at each
extremity by a tubercle. Into this line the sterno-thyroid muscle is inserted; and from it the thyro-hyoid and inferior constrictor take their origin. In the receding angle, formed by the meeting of the two alæ upon the inner side of the cartilage, and near its lower border, are attached the epiglottis, the chordaæ vocales, the thyro-arytenoid, and thyro-epiglottidean muscles.

The Cricoid (κεισος—κύος, like a ring) is a ring of cartilage, narrow in front and broad behind, where it is surmounted by two rounded surfaces, which articulate with the arytenoid cartilages. Upon the middle line, posteriorly, is a vertical ridge which gives attachment to the esophagus, and on each side of the ridge are the depressions which lodge the crico-arytenoidei postici muscles. On either side of the ring is a glenoid cavity, which articulates with the inferior cornu of the thyroid cartilage.

The Arytenoid cartilages (ἀρυταινα,* a pitcher), two in number, are triangular and prismatic in form. They are broad and thick below, where they articulate with the upper border of the cricoid cartilage; pointed above, and prolonged by two small pyriform cartilages, cornicula laryngis (capitula Santorini), which are curved inwards and backwards, and they each present three surfaces, anterior, posterior, and internal. The posterior surface is concave, and lodges part of the arytenoideus muscle; the internal surface is smooth, and forms part of the lateral wall of the larynx; the anterior or external surface is rough and irregular, and gives attachment to the chorda vocalis, thyro-arytenoideus, crico-arytenoideus lateralis and posticus, and above these to the base of the cuneiform cartilage.

The Cuneiform cartilages are two small cylinders of fibro-cartilage, about seven lines in length, and enlarged at each extremity. By the lower end, or base, the cartilage is attached to the middle of the external surface of the arytenoid, and by its upper extremity forms a prominence in the border of the aryteno-epiglottidean fold of membrane. They are sometimes wanting.

In the male the cartilages of the larynx are more or less ossified, particularly in old age.

The Epiglottis (ἰπιγλαντελς, upon the tongue) is a fibro-cartilage of a yellowish colour, studded with a number of small mucous glands, which are lodged in shallow pits upon its surface. It is shaped like a cordate leaf, and is placed immediately in front of the opening of the larynx, which it closes completely when the larynx is drawn up beneath the base of the tongue. It is attached by its point to the receding angle, between the two alæ of the thyroid cartilage.

Ligaments.—The Ligaments of the larynx are numerous, and may

* This derivation has reference to the appearance of both cartilages taken together and covered by mucous membrane. In animals, which were the principal subjects of dissection among the ancients, the opening of the larynx with the arytenoid cartilages bears a striking resemblance to the mouth of a pitcher having a large spout.
be arranged into four groups: 1. Those which articulate the thyroid with the os hyoides. 2. Those which connect it with the cricoid. 3. Ligaments of the arytenoid cartilages. 4. Ligaments of the epiglottis.

1. The ligaments which connect the thyroid cartilage with the os hyoides are three in number:—

The two Thyro-hyoidean ligaments pass between the superior cornua of the thyroid and the extremities of the greater cornua of the os hyoides: a sesamoid bone or cartilage is found in each.

The Thyro-hyoidean membrane is a broad membranous layer, occupying the entire space between the upper border of the thyroid cartilage and the upper border of the os hyoides. It is pierced by the superior laryngeal nerve and artery.

2. The ligaments connecting the thyroid to the cricoid cartilage are also three in number:—

Two Capsular ligaments, with their synovial membranes, which form the articulation between the inferior cornua of the thyroid and the sides of the cricoid; and the crico-thyroidean membrane. The crico-thyroidean membrane is a fan-shaped layer of elastic tissue, thick in front (middle crico-thyroidean ligament) and thinner at each side (lateral crico-thyroidean ligament). It is attached by its apex to the

Section of the isthmus of the thyroid gland. p, p. The levator glan- dulae thyroideae.
lower border and receding angle of the thyroid cartilage, and by its expanded margin to the upper border of the cricoid and base of the arytenoid cartilage. Superiorly it is continuous with the inferior margin of the chorda vocalis. The front of the crico-thyroidian membrane is crossed by a small artery, the inferior laryngeal, and is the spot selected for the operation of laryngotomy. Laterally it is covered in by the crico-thyroidei and crico-arytenoidei laterales muscles.

3. The ligaments of the arytenoid cartilages are six in number:—

Two Capsular ligaments, with synovial membranes, which articulate the arytenoid cartilages with the cricoid; and the superior and inferior thyro-arytenoid ligaments. The superior thyro-arytenoid ligaments are two thin bands of elastic tissue which are attached in front to the receding angle of the thyroid cartilage, and behind to the anterior and inner border of each arytenoid cartilage. The lower border of this ligament constitutes the upper boundary of the ventricle of the larynx. The inferior thyro-arytenoid ligaments or chordae vocales, are thicker than the superior, and like them composed of elastic tissue. Each ligament is attached in front to the receding angle of the thyroid cartilage, and behind to the anterior angle of the base of the arytenoid. The inferior border of the chorda vocalis is continuous with the lateral expansion of the crico-thyroid ligament. The superior border forms the lower boundary of the ventricle of the larynx. The space between the two chordae vocales is the glottis or rima glottidis.

4. The ligaments of the epiglottis are five in number, namely, three glosso-epiglottic, hyo-epiglottic, and thyro-epiglottic.

The glosso-epiglottic ligaments (fræna epiglottidis) are three folds of mucous membrane, which connect the anterior surface of the epiglottis with the root of the tongue. The middle of these contains elastic tissue. The hyo-epiglottic ligament is a band of elastic tissue passing between the anterior aspect of the epiglottis near its apex, and the upper margin of the body of the os hyoides. The thyro-epiglottic ligament is a long and slender fasciculus of elastic tissue, which embraces the apex of the epiglottis, and is inserted into the receding angle of the thyroid cartilage immediately below the anterior fissure and above the attachment of the chordae vocales.

The arytenoid cartilages. 6. The arytenoideus muscle, consisting of oblique and transverse fasciculi. 7. The crico-arytenoidei post-tici muscles. 8. The epiglottis.
Muscles.—The Muscles of the larynx are eight in number: the five larger are the muscles of the chordae vocales and rima glottidis; the three smaller are muscles of the epiglottis.

The five muscles of the chordae vocales and rima glottidis are the—

- Crico-thyroid,
- Crico-arytenoideus posticus,
- Crico-arytenoideus lateralis,
- Thyro-arytenoideus,
- Arytenoideus.

The Crico-thyroid muscle arises from the anterior surface of the cricoid cartilage, and passes obliquely outwards and backwards to be inserted into the lower and inner border of the ala of the thyroid as far back as its inferior cornu.

The Crico-arytenoideus posticus arises from the depression on the posterior surface of the cricoid cartilage, and passes upwards and outwards to be inserted into the outer angle of the base of the arytenoid.

The Crico-arytenoideus lateralis arises from the upper border of the side of the cricoid, and passes upwards and backwards to be inserted into the outer angle of the base of the arytenoid cartilage.

The Thyro-arytenoideus arises from the receding angle of the thyroid cartilage, close to the outer side of the chorda vocalis, and passes backwards parallel with the cord, to be inserted into the base and outer surface of the arytenoid cartilage.

The Arytenoideus muscle occupies the posterior concave surface of the arytenoid cartilages, between which it is stretched. It consists of three planes of transverse and oblique fibres; hence it was formerly considered as several muscles, under the names of transversi and obliqui.

The three muscles of the epiglottis are the—

- Thyro-epiglottideus,
- Arytendo-epiglottideus superior,
- Arytendo-epiglottideus inferior (Hilton’s muscle).

* A side view of the larynx, one ala of the thyroid cartilage has been removed. 1. The remaining ala of the thyroid cartilage. 2. One of the arytenoid cartilages. 3. One of the cornicula laryngis. 4. The cricoid cartilage. 5. The crico-arytenoideus posticus muscle. 6. The crico-arytenoideus lateralis. 7. The thyro-arytenoideus. 8. The crico-thyroidean membrane. 9. One half of the epiglottis. 10. The upper part of the trachea.
The *Thyro-epiglottideus* appears to be formed by the upper fibres of the thyro-arytenoidei muscle: they spread out upon the external surface of the sacculus laryngis and in the aryteno-epiglottidean fold of mucous membrane, in which they are lost; a few of the anterior fibres being continued onwards to the side of the epiglottis.

The *Aryteno-epiglottideus superior* consists of a few scattered fibres, which pass forwards in the fold of mucous membrane forming the lateral boundary of the entrance into the larynx, from the apex of the arytenoid cartilage to the side of the epiglottis.

The *Aryteno-epiglottideus inferior*.—This muscle, described by Mr. Hilton, is very important in relation to the sacculus laryngis, with which it is closely connected. It may be found by raising the mucous membrane immediately above the ventricle of the larynx. It arises by a narrow and fibrous origin from the arytenoid cartilage, just above the attachment of the chorda vocalis; and passing forwards, and a little upwards, expands over the upper half, or two-thirds of the sacculus laryngis, and is inserted by a broad attachment into the side of the epiglottis.

*Actions.*—From a careful investigation of the muscles of the larynx Mr. Bishop* concludes that the crico-arytenoidei postici open the glottis, while all the rest close it. The arytenoidei approximates the arytenoid cartilages posteriorly, and the crico-arytenoidei and thyro-arytenoidei anteriorly; the latter, moreover, close the glottis mesially. The crico-thyroidei are tensors of the chordæ vocales, and these muscles, together with the thyro-arytenoidei regulate the tension, position, and vibrating length of the vocal cords.

The crico-thyroid muscles effect the tension of the chordæ vocales by rotating the cricoid on the inferior cornua of the thyroid; by this action the anterior portion is drawn upwards and made to approximate the inferior border of the thyroid, while the posterior and superior border of the cricoid, together with the arytenoid cartilages, is carried backwards. The crico-arytenoidei postici separate the chordæ vocales by drawing the arytenoid cartilages outwards and downwards. The crico-arytenoidei laterales, by drawing the outer angles of the arytenoid cartilages forwards, approximate the anterior angles to which the chordæ vocales are attached. The thyro-arytenoidei draw the arytenoid cartilages forwards, and, by their connection with the chordæ vocales, act upon the whole length of those cords.

The thyro-epiglottideus acts principally by compressing the glands of the sacculus laryngis and the sac itself; by its attachment to the epiglottis it would act feebly upon that valve. The aryteno-epiglottideus superior serves to keep the mucous membrane of the sides of the opening of the glottis tense, when the larynx is drawn upwards, and the opening closed by the epiglottis. Of the aryteno-epiglottideus, the "functions appear to be," writes Mr. Hilton, "to compress the subjacent glands which open into the pouch; to diminish the capacity

* Cyclopædia of Anatomy and Physiology. Article, Larynx.
of that cavity, and change its form; and to approximate the epiglottis and the arytenoid cartilage.”

*Mucous membrane.*—The aperture of the larynx is a triangular, or cordiform opening, broad in front and narrow behind; bounded anteriorly by the epiglottis, posteriorly by the arytenoideus muscle, and on either side by a fold of mucous membrane stretched between the side of the epiglottis and the apex of the arytenoid cartilage. On the margin of this *aryteto-epiglottidean* fold the cuneiform cartilage forms a prominence more or less distinct. The cavity of the larynx is divided into two parts by an oblong constriction produced by the prominence of the chordae vocales. That portion of the cavity which lies above the constriction is broad and triangular above, and narrow below; that which is below is narrow above and broad and cylindrical below, the circumference of the cylinder corresponding with the ring of the cricoid; while the space included by the constriction is a narrow, triangular fissure, the *glottis* or *rina glottidis*. The form of the glottis is that of an isosceles triangle, bounded on the sides by the chordae vocales and inner surface of the arytenoid cartilages, and behind by the arytenoideos muscle. Its length is greater in the male than in the female, and in the former measures somewhat less than an inch. Immediately above the prominence caused by the chorda vocalis, and extending nearly its entire length on each side of the cavity of the larynx, is an elliptical fossa, the *ventricle of the larynx*. This fossa is bounded below by the chorda vocalis, which it serves to isolate, and above by a border of mucous membrane folded upon the lower edge of the superior thyro-arytenoid ligament. The whole of the cavity of the larynx with its prominences and depressions, is lined by mucous membrane, which is continuous superiorly with that of the mouth and pharynx, and inferiorly is prolonged through the trachea and bronchial tubes into the air cells of the lungs. In the ventricles of the larynx the mucous membrane forms a caecal pouch of variable size, termed by Mr. Hilton the *sacculus laryngis.* The sacculus laryngis is directed

*This sac was described by Mr. Hilton before he was aware that it had already been pointed out by the older anatomists. I myself made a dissection, which I still possess, of the same sac in an enlarged state, during the month of August, 1837, without any knowledge either of Mr. Hilton’s labours, or Morgagni’s account. The sac projected considerably above the upper border of the thyroid cartilage, and the extremity had been snipped off on one side in the removal of the muscles. The larynx was presented to me by Dr. George Moore of Camberwell; he had obtained it from a child who died of bronchial disease; and he conceived that this peculiar disposition of the mucous membrane might possibly explain some of the symptoms by which the case was accompanied. Cruveilhier made the same observation in equal ignorance of Morgagni’s description, for we read in a note at page 677, vol. ii. of his *Anatomie Descriptive*—‘‘*J’ai vu pour la première fois cette arrière cavité chez un individu affecté de phthisie laryngée, où elle était très-développée. Je fis des recherches sur le larynx d’autres individus, et je trouval que cette disposition était constante. Je ne savais pas alors que Morgagni avait indiqué et fait représenter la même disposition.’’* Cruveilhier compares its form very aptly to a
upwards, sometimes extending as high as the upper border of the thyroid cartilage, and occasionally above that border. When dissected from the interior of the larynx it is found covered by the aryteno-epiglottideus muscle and a fibrous membrane, which latter is attached to the superior thyro-arytenoid ligament below; to the epiglottis in front; and to the upper border of the thyroid cartilage above. If examined from the exterior of the larynx, it will be seen to be covered by the thyroepiglottideus muscle. On the surface of its mucous membrane are the openings of sixty or seventy small follicular glands, which are situated in the sub-mucous tissue, and gives to its external surface a rough and ill-dissected appearance. This mucous secretion is intended for the lubrication of the chordae vocales, and is directed upon them by two small valvular folds of mucous membrane, which are situated at the entrance of the sacculus.

Glands.—The bodies known as the glands of the larynx, namely, the epiglottic and the arytenoid are very improperly named. The former is a mass of areolar and adipose tissue, situated in the triangular space between the front surface of the apex of the epiglottis, the hyoepiglottidean and the thyro-hyoidean ligament. The latter is the body which forms a prominence in the aryteno-epiglottidean fold of mucous membrane, and has been described among the cartilages as the arytenoid cartilage.

Vessels and Nerves.—The Arteries of the larynx are derived from the superior and inferior thyroid. The nerves are the superior laryngeal and recurrent laryngeal; both branches of the pneumogastric. The two nerves communicate with each other freely; but the superior laryngeal is distributed principally to the mucous membrane at the entrance of the larynx; the recurrent, to the muscles.

THE TRACHEA.

The Trachea extends from opposite the fifth cervical vertebra to opposite the third dorsal, where it divides into the two bronchi. The right bronchus, larger than the left, passes off nearly at right angles to the upper part of the corresponding lung. The left descends obliquely, and passes beneath the arch of the aorta, to reach the left lung.

The Trachea is composed of—

Fibro-cartilaginous rings,
Fibrous membrane,
Mucous membrane,
Longitudinal elastic fibres,
Muscular fibres,
Glands.

"Phrygian casque," and Morgagni's figure, Advers. 1. Epist. Anat. 3. plate 2. fig. 4. has the same appearance. But neither of these anatomists notice the follicular glands described by Mr. Hilton.
The Fibro-cartilaginous rings are from fifteen to twenty in number, and extend for two-thirds around the cylinder of the trachea. They are deficient at the posterior part, where the tube is completed by fibrous membrane. The last ring has usually a triangular form in front. The rings are connected to each other by a membrane of yellow elastic fibrous tissue, which in the space between the extremities of the cartilages, posteriorly, forms a distinct layer.

The Longitudinal elastic fibres are situated immediately beneath the mucous membrane on the posterior part of the trachea, and enclose the entire cylinder of the bronchial tubes to their ultimate terminations.

The Muscular fibres form a thin layer, extending transversely between the extremities of the cartilages. On the posterior surface they are covered in by a cellulo-fibrous lamella, in which are lodged the tracheal glands. These are small flattened ovoid bodies, situated in great number between the fibrous and muscular layers of the membranous portion of the trachea, and also between the two layers of elastic fibrous tissue connecting the rings. They pour their secretion upon the mucous membrane.

**Thyroid Gland.**

The thyroid gland or body is one of those organs which it is difficult to classify from the absence of any positive knowledge with regard to its function. It is situated upon the trachea, and in an anatomical arrangement may therefore be considered in this place, although bearing no part in the function of respiration.

This gland consists of two lobes, which are placed one on each side of the trachea, and are connected with each other by means of an isthmus, which crosses its upper rings. There is considerable variety in the situation and breadth of this isthmus; which should be recollected in the performance of operations upon the trachea. In structure it appears to be composed of a dense cellular parenchyma, enclosing a great number of vessels. The gland is larger in young subjects and in females, than in the adult and males. It is the seat of an enlargement called bronchocele, goitre, or the Derbyshire neck.

A muscle is occasionally found connected with its upper border or with its isthmus; and attached, superiorly, to the body of the os hyoïdes, or to the thyroid cartilage. It was named by Soemmering the "levator glandulae thyroidea," fig. 163, p. 543.

Vessels and Nerves.—It is abundantly supplied with blood by the superior and inferior thyroid arteries. Sometimes an additional artery is derived from the arteria innominata, and ascends upon the front of the trachea to be distributed to the gland. The wounding of this vessel, in tracheotomy, might be fatal to the patient. The nerves are derived from the superior laryngeal and sympathetic.
The lungs are two conical organs, situated one on each side of the chest, embracing the heart, and separated from each other by that organ and by a membranous partition, the mediastinum. On the external or thoracic side they are convex, and correspond with the form of the cavity of the chest; internally they are concave, to receive the convexity of the heart. Superiorly they terminate in a tapering cone, which extends above the level of the first rib, and inferiorly they are broad and concave, and rest upon the convex surface of the diaphragm.

*Anatomy of the heart and lungs. 1. The right ventricle; the vessels to the right of the figure are the middle coronary artery and veins; and those to its left, the anterior coronary artery and veins. 2. The left ventricle. 3. The right auricle. 4. The left auricle. 5. The pulmonary artery. 6. The right pulmonary artery. 7. The left pulmonary artery. 8. The remains of the ductus arteriosus. 9. The arch of the aorta. 10. The superior vena cava. 11. The right artery innominata, and in front of it the vena innominata. 12. The right subclavian vein, and behind it its corresponding artery. 13. The right common carotid artery and vein. 14. The left vena innominata. 15. The left carotid artery and vein. 16. The left subclavian vein and artery. 17. The trachea. 18. The right bronchus. 19. The left bronchus. 20, 20. The pulmonary veins; 18, 20, form the root of the right lung; and 7, 19, 20, the root of the left. 21. The superior lobe of the right lung. 22. Its middle lobe. 23. Its inferior lobe. 24. The superior lobe of the left lung. 25. Its inferior lobe.
Their posterior border is rounded and broad, the anterior sharp, and 
marked by one or two deep fissures, and the inferior border which 
surrounds the base is also sharp. The colour of the lungs is pinkish 
grey, mottled, and variously marked with black. The surface is 
figured with irregularly polygonal outlines, which represent the lobules 
of the organ, and the area of each of these polygonal spaces is crossed 
by lighter lines.

Each lung is divided into two lobes, by a long and deep fissure, 
which extends from the posterior surface of the upper part of the 
organ, downwards and forwards to near the anterior angle of its base. 
In the right lung the upper lobe is subdivided by a second fissure, 
which extends obliquely forwards from the middle of the preceding to 
the anterior border of the organ, and marks off a small triangular 
lobe.

The right lung is larger than the left, in consequence of the inclina-
tion of the heart to the left side. It is also shorter, from the great 
convexity of the liver, which presses the diaphragm upwards upon the 
right side of the chest considerably above the level of the left; and has 
three lobes. The left lung is smaller, has but two lobes, but is longer 
than the right.

Each lung is retained in its place by its root, which is formed by the 
pulmonary artery, pulmonary veins and bronchial tubes, together with 
the bronchial vessels and pulmonary plexuses of nerves. The large 
vessels of the root of each lung are arranged in a similar order from 
before, backwards, on both sides, viz.

Pulmonary veins, 
Pulmonary artery, 
Bronchus.

From above, downwards, on the right side this order is exactly re-
versed; but on the left side the bronchus has to stoop beneath the 
arch of the aorta, which alters its position to the vessels. They are 
thus disposed on the two sides:—

Structure. — The lungs are composed of the ramifications of the 
bronchial tubes which terminate in bronchial cells (air cells), of the 
ramifications of the pulmonary artery and veins, bronchial arteries and 
veins, lymphatics and nerves; the whole of these structures being held 
gether by areolar tissue, constitute the parenchyma. The parenchyma 
of the lungs, when examined on the surface or by means of a section, 
is seen to consist of small polygonal divisions, or lobules, which are 
connected to each other by an inter-lobular areolar tissue. These
lobules again consist of smaller lobules, and the latter are formed by a cluster of air cells, in the parietes of which the capillaries of the pulmonary artery and pulmonary veins are distributed.

**Bronchial tubes.** — The two bronchi proceed from the bifurcation of the trachea to their corresponding lungs. The right takes its course nearly at right angles with the trachea, and enters the upper part of the right lung; while the left, longer and smaller than the right, passes obliquely beneath the arch of the aorta, and enters the lung at about the middle of its root. Upon entering the lungs they divide into two branches, and each of these divides and subdivides dichotomously to their ultimate termination in small dilated sacs, the bronchial or pulmonary cells. The fibro-cartilaginous rings which are observed in the trachea become incomplete and irregular in shape in the bronchi, and in the smaller bronchial tubes are lost altogether. At the termination of these tubes the fibrous and muscular coats become extremely thin, and are probably continued upon the lining mucous membrane of the air cells.

The **Pulmonary artery**, conveying the dark and impure venous blood to the lungs, terminates in capillary vessels, which form a minute network upon the parietes of the bronchial cells, and then converge to form the pulmonary veins, by which the arterial blood, purified in its passage through the capillaries, is returned to the left auricle of the heart.

The **Bronchial arteries**, branches of the thoracic aorta, ramify upon the bronchial tubes and in the tissue of the lungs, and supply them with nutrition, while the venous blood is returned by the bronchial veins to the vena azygos.

The **Lymphatics**, commencing upon the surface and in the substance of the lungs, terminate in the bronchial glands. These glands, very numerous and often of large size, are placed at the roots of the lungs, around the bronchi, and at the bifurcation of the trachea. In early life they resemble lymphatic glands in other situations; but in old age, and often in the adult, are quite black, and filled with carbonaceous matter, and occasionally with calcareous deposits.

The **Nerves** are derived from the pneumogastric and sympathetic. They form two plexuses, *anterior pulmonary plexus*, situated upon the front of the root of the lungs, and composed chiefly of filaments from the great cardiac plexus; and *posterior pulmonary plexus* on the posterior aspect of the root of the lungs, composed principally of branches from the pneumogastric. The branches from these plexuses follow the course of the bronchial tubes, and are distributed to the bronchial cells.

**PLEURE.**

Each lung is enclosed, and its structure maintained, by a serous membrane, the pleura, which invests it as far as the root, and is then reflected upon the parieties of the chest. That portion of the
membrane which is in relation with the lung is called pleura pulmonalis, and that in contact with the parietes, pleura costalis. The reflected portion, besides forming the internal lining to the ribs and intercostal muscles, also covers the diaphragm and the thoracic surface of the vessels at the root of the neck.

The pleura must be dissected from off the root of the lung, to see the vessels by which it is formed and the pulmonary plexuses.

MEDIASTINUM.

The approximation of the two reflected pleuræ in the middle line of the thorax forms a septum, which divides the chest into the two pulmonary cavities. This is the mediastinum. The two pleuræ are not, however, in contact with each other at the middle line in the formation of the mediastinum, but leave a space between them which contains all the viscera of the chest with the exception of the lungs. The mediastinum is divided into the anterior, middle, and posterior.

The Anterior mediastinum is a triangular space, bounded in front by the sternum, and on each side by the pleura. It contains a quantity of loose areolar tissue, in which are found some lymphatic glands and vessels passing upwards from the liver; the remains of the thymus gland, the origins of the sterno-hyoid, sterno-thyroid, and triangularis sterni muscles, and the internal mammary vessels of the left side.

The Middle mediastinum contains the heart enclosed in its pericardium; the ascending aorta; the superior vena cava; the bifurcation of the trachea; the pulmonary arteries and veins; and the phrenic nerves.

The Posterior mediastinum is bounded behind by the vertebral column, in front by the pericardium, and on each side by the pleura. It contains the descending aorta; the greater and lesser azygos veins, the superior intercostal vein; the thoracic duct; the œsophagus and pneumogastric nerves; and the great splanchnic nerves.

ABDOMEN.

The abdomen is the inferior cavity of the trunk of the body; it is bounded in front and at the sides by the lower ribs and abdominal muscles; behind, by the vertebral column and abdominal muscles; above, by the diaphragm; and, below, by the pelvis: and contains the alimentary canal, the organs subservient to digestion, viz. the liver, pancreas, and spleen; and the organs of excretion, the kidneys, with the supra-renal capsules.

Regions.—For convenience of description of the viscera, and for reference to the morbid affections of this cavity, the abdomen is divided into certain districts or regions. Thus, if two transverse lines be carried around the body, the one parallel with the convexities of the
ribs, the other with the highest points of the crests of the ilia, the abdomen will be divided into three zones. Again, if a perpendicular line be drawn at each side, from the cartilage of the eighth rib to the middle of Poupart's ligament, the three primary zones will each be subdivided into three compartments or regions, a middle and two lateral.

The middle region of the upper zone being immediately over the small end of the stomach, is called epigastric (ἐπιγάστριος, over the stomach). The two lateral regions being under the cartilages of the ribs are called hypochondriac (ὑποκόνδυλος, under the cartilages). The middle region of the middle zone is the umbilical; the two lateral, the lumbar. The middle region of the inferior zone is the hypogastric (ὑπογαστρικός, below the stomach); and the two lateral, the iliac. In addition to these divisions, we employ the term inguinal region, in reference to the vicinity of Poupart's ligament.

Position of the Viscera.—In the upper zone will be seen the liver, extending across from the right to the left side; the stomach and spleen on the left, and the pancreas and duodenum behind. In the middle zone is the transverse portion of the colon, with the upper part of the ascending and descending colon, omentum, small intestines, mesentery, and, behind, the kidneys and supra-renal capsules. In the inferior zone is the lower part of the omentum and small intestines, the cæcum, ascending and descending colon with the sigmoid flexure, and ureters.

The smooth and polished surface, which the viscera and parietes of the abdomen present, is due to the peritoneum, which should in the next place be studied.

PERITONEUM.

The Peritoneum (περιτόνειον, to extend around) is a serous membrane, and therefore a shut sac: a single exception exists in the human subject to this character, viz. in the female, where the peritoneum is perforated by the open extremities of the Fallopian tubes, and is continuous with their mucous lining.

The simplest idea that can be given of a serous membrane, which may apply equally to all, is, that it invests the viscus or viscera, and is then reflected upon the parietes of the containing cavity. If the cavity contain only a single viscus, the consideration of the serous membrane is extremely simple. But in the abdomen, where there are a number of viscera, the serous membrane passes from one to the other until it has invested the whole, before it is reflected on the parietes. Hence its reflexions are a little more complicated.

In tracing the reflexions of the peritoneum in the middle line, we commence with the diaphragm, which is lined by two layers, one from the parietes in front, anterior, and one from the parietes behind, posterior. These two layers of the same membrane, at the posterior part of the diaphragm, descend to the upper surface of the liver,
forming the *coronary* and *lateral ligaments* of the liver. They then surround the liver, one going in front, the other behind that viscus, and, meeting at its under surface, pass to the stomach, forming the

The posterior layer traced upwards in front
lesser omentum. They then, in the same manner, surround the stomach, and meeting at its lower border, descend for some distance in front of the intestines, and return to the transverse colon, forming the great omentum; they then surround the transverse colon, and pass directly backwards to the vertebral column, forming the transverse meso-colon. Here the two layers separate; the posterior ascends in front of the pancreas and aorta, and returns to the posterior part of the diaphragm, where it becomes the posterior layer with which we commenced. The anterior descends, invests all the small intestines, and returning to the vertebral column forms the mesentery. It then descends into the pelvis in front of the rectum, which it holds in its place by means of a fold called meso-rectum, forms a pouch, the recto-vesical fold, between the rectum and bladder, ascends upon the posterior surface of the bladder, forming its false ligaments, and returns upon the anterior parietes of the abdomen to the diaphragm, whence we first traced it.

In the female, after descending into the pelvis in front of the rectum, it is reflected upon the posterior surface of the vagina and uterus. It then descends on the anterior surface of the uterus, and forms at either side the broad ligaments of that organ. From the uterus it ascends upon the posterior surface of the bladder and anterior parietes of the abdomen, and is continued, as in the male, to the diaphragm.

In this way the continuity of the peritoneum, as a whole, is distinctly shown, and it matters not where the examination commence or where it terminate, still the same continuity of surface will be discernible throughout. If we trace it from side to side of the abdomen, we may commence at the umbilicus; we then follow it outwards lining the inner side of the parietes to the ascending colon; it surrounds that intestine; it then surrounds the small intestine, and returning on itself forms the mesentery. It then invests the descending colon, and reaches the parietes on the opposite side of the abdomen, whence it may be traced to the exact point from which we started.

The viscera, which are thus shown to be invested by the peritoneum in its course from above downwards, are the—

Liver,  
Stomach,  
Transverse colon,  
Small intestines,  
Pelvic viscera.

of D, the transverse duodenum, and P, the pancreas, to become continuous with the posterior layer (2). 9. The foramen of Winslow; the dotted line bounding this foramen inferiorly marks the course of the hepatic artery forwards, to enter between the layers of the lesser omentum. 10. The mesentery encircling the small intestine. 11. The recto-vesical fold, formed by the descending anterior layer. 12. The anterior layer traced upwards upon the internal surface of the abdominal parietes to the layer (1), with which the examination commenced.
The folds, formed between these and between the diaphragm and the liver, are—

(Diaphragm.)
Broad, coronary, and lateral ligaments.

(Liver.)
Lesser omentum.

(Stomach.)
Greater omentum.

(Transverse colon.)
Transverse meso-colon,

Mesentery,
Meso-rectum,
Recto-vesical fold,
False ligaments of the bladder.

And in the female, the—

Broad ligaments of the uterus.

The ligaments of the liver will be examined with that organ.

The Lesser omentum is the duplicature passing between the liver and the upper border of the stomach. It is extremely thin, excepting at its right border, where it is free, and contains between its layers, the—

Hepatic artery,
Ductus communis choledochus,
Portal vein,
Hepatic plexus of nerves,
Lymphatics.

These structures are enclosed in a loose areolar tissue, called Glisson's capsule.* The relative position of the three vessels is, the artery to the left, the duct to the right, and the vein between and behind.

If the finger be introduced behind this right border of the lesser omentum, it will be situated in an opening called the foramen of Winslow.† In front of the finger will lie the right border of the lesser omentum; behind it the diaphragm, covered by the ascending or posterior layer of the peritoneum; below, the hepatic artery, curving forwards from the cæliac axis; and above, the lobus Spigelii. These, therefore, are the boundaries of the foramen of Winslow, which is nothing more than a constriction of the general cavity of the peritoneum

* Francis Glisson, Professor of Medicine in the University of Cambridge. His work, “De Anatomia Hepatis,” was published in 1654
† Jacob Benignus Winslow: his “Exposition Anatomique de la Structure du Corps Humain,” was published in Paris in 1732.
at this point, arising out of the necessity for the hepatic and gastric arteries to pass forwards from the cæliac axis to reach their respective viscera.

If air be blown through the foramen of Winslow, it will descend behind the lesser omentum and stomach to the space between the descending and ascending pair of layers, forming the great omentum. This is sometimes called the lesser cavity of the peritoneum, and that external to the foramen the greater cavity; in which case the foramen is considered as the means of communication between the two. There is a great objection to this division, as it might lead the inexperienced to believe that there were really two cavities. There is but one only, the foramen of Winslow being merely a constriction of that one, to facilitate the communication between the nutrient arteries and the viscera of the upper part of the abdomen.

The Great omentum consists of four layers of peritoneum, the two which descend from the stomach, and the same two, returning upon themselves to the transverse colon. A quantity of adipose substance is deposited around the vessels which ramify through its structure. It would appear to perform a double function in the economy. 1st. Protecting the intestines from cold; and, 2ndly. Facilitating the movement of the intestines upon each other during their vermicular action.

The Transverse meso-colon (μίσως, middle, being attached to the middle of the cylinder of the intestine) is the medium of connection between the transverse colon and the posterior wall of the abdomen. It also affords to the nutrient arteries a passage to reach the intestine, and encloses between its layers, at the posterior part, the transverse portion of the duodenum.

The Mesentery (μίσως ἐντερον, being connected to the middle of the cylinder of the small intestine) is the medium of connection between the small intestines and the posterior wall of the abdomen. It is oblique in its direction, being attached to the posterior wall, from the left side of the second lumbar vertebra to the right iliac fossa. It retains the small intestines in their places, and gives passages to the mesenteric arteries, veins, nerves, and lymphatics.

The Meso-rectum, in like manner, retains the rectum in connection with the front of the sacrum. Besides this, there are some minor folds in the pelvis, as the recto-vesical fold, the false ligaments of the bladder, and the broad ligaments of the uterus.

The Appendices epiploicae are small irregular pouches of the peritoneum, filled with fat, and situated like fringes upon the large intestine.

Three other duplicatures of the peritoneum are situated in the sides of the abdomen; they are the gastro-phrenic ligament, the gastro-splenic omentum, the ascending and descending meso-colon. The gastro-phrenic ligament is a small duplicature of the peritoneum, which descends from the diaphragm to the extremity of the oesophagus, and lesser curve of the stomach. The gastro-splenic omentum is the duplicature which connects the spleen to the stomach. The ascending
meso-colon is the fold which connects the upper part of the ascending colon with the posterior wall of the abdomen; and the descending meso-colon, that which retains the sigmoid flexure in connection with the abdominal wall.

Structure of serous membrane.—Serous membrane consists of two layers, an external or fibro-cellular layer, and an internal layer or epithelium. The fibro-cellular layer upon its outer surface is rough and vascular, and adherent to surrounding structures; but on its inner surface is dense and smooth, and wholly deficient of vessels carrying red blood. The smooth and brilliant surface of serous membrane is due to a distinct epithelium, which has been shown by the excellent researches of Henle, to be composed of laminae of vesicles, and flattened polygonal scales with central nuclei, like the epidermis and epithelium of mucous membrane. Dr. Henle has observed this structure, which may be easily demonstrated with a good microscope upon the surface of all the serous membranes of the body, upon the surface of the lining membrane of arteries and veins, and upon synovial membranes.

The general characters of a serous membrane are its resemblance to a shut sac, and its secretion of a peculiar fluid, resembling the serum of the blood; but the former of these characters is not absolutely essential to the identity of a serous membrane; for, as we have shown above, the peritoneum in the female is perforated by the extremities of the Fallopian tubes; while in aquatic reptiles there is a direct communication between its cavity and the medium in which they live.

From the variable nature of the secretion of these membranes, they have been divided into two classes, the true serous membranes, viz. the arachnoid, pericardium, pleurae, peritoneum, and tunicae vaginales, which pour out a secretion containing but a small portion of albumen; and the synovial membranes and bursæ, which secrete a fluid containing a larger quantity of albumen.

ALIMENTARY CANAL.

The Alimentary canal is a musculo-membranous tube, extending from the mouth to the anus. It is variously named in the different parts of its course; hence it is divided into the

Mouth,
Pharynx,
Œsophagus,
Stomach,
Small intestine  { Duodenum,
                   Jejunum,
                   Ileum,
                   Caecum,
Large intestine  { Colon,
                   Rectum.
The Mouth is the irregular cavity which contains the organs of taste and the principal instruments of mastication. It is bounded in front by the lips; on either side by the internal surface of the cheeks; above by the hard palate and teeth of the upper jaw; below by the tongue, by the mucous membrane stretched between the arch of the lower jaw and the under surface of the tongue, and by the teeth of the inferior maxilla; and behind by the soft palate and faucæ.

The Lips are two fleshy folds formed externally by common integument, and internally by mucous membrane, and containing between these two layers the muscles of the lips, a quantity of fat, and numerous small labial glands. They are attached to the surface of the upper and lower jaw, and each lip is connected to the gum in the middle line by a fold of mucous membrane, the fraenum labii superioris and fraenum labii inferioris, the former being the larger.

The Cheeks (buccæ) are continuous on either hand with the lips, and form the sides of the face; they are composed of integument, a large quantity of fat, muscles, mucous membrane, and buccal glands.

The mucous membrane lining the cheeks is reflected above and below upon the sides of the jaws, and is attached posteriorly to the anterior margin of the ramus of the lower jaw. At about its middle, opposite the second molar tooth of the upper jaw, is a papilla, upon which may be observed a small opening, the aperture of the duct of the parotid gland.

The Hard palate is a dense structure, composed of mucous membrane, palatal glands, fibrous tissue, vessels, and nerves, and firmly connected to the palate processes of the superior maxillary and palate bones. It is bounded in front and on each side by the alveolar processes and gums, and is continuous behind with the soft palate. Along the middle line it is marked by an elevated raphé, and presents upon each side of the raphé a number of transverse ridges and grooves. Near its anterior extremity, and immediately behind the middle incisor teeth, is a papilla which corresponds with the termination of the nasopalatine canal, and has been supposed to be endowed with a peculiar sensibility.

The Gums are composed of a thick and dense mucous membrane, which is closely adherent to the periosteum of the alveolar processes, and embraces the necks of the teeth. They are remarkable for their hardness and insensibility; and for their close contact, without adhesion, to the surface of the tooth. From the neck of the tooth they are reflected into the alveolus, and become continuous with the periosteal membrane of that cavity.

The Tongue has been already described as an organ of sense; it is invested by mucous membrane, which is reflected from its under part upon the inner surface of the lower jaw, and constitutes, with the muscles beneath, the floor of the mouth. Upon the under surface of the tongue, near its anterior part, the mucous membrane forms a considerable fold, which is called the fraenum linguae; and on each side of the fraenum is a large papilla, the commencement of the duct of the
submaxillary gland, and several smaller openings, the ducts of the sublingual gland.

The Soft palate (velum pendulum palati) is a fold of mucous membrane situated at the posterior part of the mouth. It is continuous, superiorly, with the hard palate, and is composed of mucous membrane, palatal glands, and muscles. Hanging from the middle of its inferior border is a small rounded process, the uvula; and passing outwards from the uvula on each side are two curved folds of the mucous membrane, the arches, or pillars of the palate. The anterior pillar is continued downwards to the side of the base of the tongue, and is formed by the projection of the palato-glossus muscle. The posterior pillar is prolonged downwards and backwards into the pharynx, and is formed by the convexity of the palato-pharyngus muscle. These two pillars, closely united above, are separated below by a triangular interval or niche, in which the tonsil is lodged.

The Tonsils (amygdalae) are two glandular organs, shaped like almonds, and situated between the anterior and posterior pillar of the soft palate, on each side of the fauces. They are cellular in texture, and composed of an assemblage of mucous follicles, which open upon the surface of the gland. Externally, they are invested by the pharyngeal fascia, which separates them from the superior constrictor muscle and internal carotid artery, and prevents an abscess from opening in that direction. In relation to surrounding parts, they correspond with the angle of the lower jaw.

The space included between the soft palate and the root of the tongue is the isthmus of the fauces. It is bounded above by the soft palate; on each side by the pillars of the soft palate and tonsils; and below by the root of the tongue. It is the opening between the mouth and pharynx.

SALIVARY GLANDS.

Communicating with the mouth are the excreatory ducts of three pairs of salivary glands, the parotid, submaxillary, and sublingual.

The Parotid gland (παρός, near, ὀὖς, ὄτος, the ear,) the largest of the three, is situated immediately in front of the external ear, and extends superficially for a short distance over the masseter muscle, and deeply behind the ramus of the lower jaw. It reaches inferiorly to below the level of the angle of the lower jaw, and posteriorly to the mastoid process, slightly overlapping the insertion of the sterno-mastoid muscle. Embedded in its substance are the external carotid artery, temporo-maxillary vein, and facial nerve; emerging from its anterior border, the transverse facial artery and branches of the pes anserinus; and above, the temporal artery.

The duct of the parotid gland (Stenon's* duct) commences at the

* Nicholas Stenon, an anatomist of great research. He discovered the parotid duct while in Paris. He was appointed professor of Medicine in Copen-
papilla upon the internal surface of the cheek, opposite the second molar tooth of the upper jaw; and, piercing the buccinator muscle, crosses the masseter to the anterior border of the gland, where it divides into several branches, which subdivide and ramify through its structure, to terminate in the small caecal pouches of which the gland is composed. A small branch is generally given off from the duct while crossing the masseter muscle, which forms, by its ramifications and terminal dilatations, a small glandular appendage, the socia parotidis. Stenon’s duct is remarkably dense and of considerable thickness, while the area of its canal is extremely small.

The Submaxillary gland is situated in the posterior angle of the submaxillary triangle of the neck. It rests upon the hyo-glossus and mylo-hyoidus muscles, and is covered in by the body of the lower jaw and by the deep cervical fascia. It is separated from the parotid gland by the stylo-maxillary ligament, and from the sublingual by the mylo-hyoidus muscle. Embedded among its lobules are the facial artery and submaxillary ganglion.

The excretory duct (Wharton’s) of the submaxillary gland commences upon the papilla, by the side of the frænum linguae, and passes backwards beneath the mylo-hyoides and resting upon the hyo-glossus muscle, to the middle of the gland, where it divides into numerous branches, which ramify through the structure of the gland to its caecal terminations. It lies in its course against the mucous membrane forming the floor of the mouth, and causes a prominence of that membrane.

The Sublingual is an elongated and flattened gland, situated beneath the mucous membrane of the floor of the mouth, on each side of the frænum linguae. It is in relation above with the mucous membrane; in front with the depression by the side of the symphysis of the lower jaw; externally with the mylo-hyoidus muscle; and internally with the hypoglossal nerve and genio-hyo-glossus muscle.

It pours its secretion into the mouth by seven or eight small ducts, which commence by small openings on each side of the frænum linguae.

Structure.—The salivary are conglomerate glands, consisting of lobes, which are made up of polygonal lobules, and these of still smaller lobules.

The smallest lobule is apparently composed of granules, which are minute caecal pouches, formed by the dilatation of the extreme ramifications of the ducts. These minute ducts unite to form lobular ducts, and the lobular ducts constitute by their union a single excretory duct. The caecal pouches are connected by areolar tissue, so as to form a minute lobule; the lobules are held together by a more condensed areolar layer; and the larger lobes are enveloped by a dense cellulo-fibrous capsule, which is firmly attached to the deep cervical fascia.

Hagen in 1672. His work, ‘‘De Musculis et Glandulis Observationes,’’ was published in 1664.
Vessels and Nerves.—The parotid gland is abundantly supplied with arteries by the external carotid; the submaxillary by facial; and the sublingual by the sublingual branch of the lingual artery.

The Nerves of the parotid gland are derived from the auricular branch of the inferior maxillary, from the auricularis magnus, and from the nervi molles of the external carotid artery. The submaxillary gland is supplied by the branches of the submaxillary ganglion, and by filaments from the mylo-hyoidian nerve; and the sublingual by filaments from the submaxillary ganglion and gustatory nerve.

PHARYNX.

The pharynx (pharynx, the throat) is a musculo-membranous sac, situated upon the cervical portion of the vertebral column, and extending from the base of the skull to a point corresponding with the cricoid cartilage in front, and the fifth cervical vertebra behind. It is composed of mucous membrane, muscles, vessels, and nerves, and is invested by a strong fascia, situated between the mucous membrane and muscles, which serves to connect it with the basilar process of the occipital bone and with the petrous portions of the temporal bones. Upon its anterior part it is incomplete, and has opening into it seven foramina, viz.

Posterior nares, two,
Eustachian tubes, two,
Mouth,
Larynx,
Esophagus.

The Posterior nares are the two large openings at the upper and front part of the pharynx. On each side of these openings, and slightly

*The pharynx laid open from behind. 1. A section carried transversely through the base of the skull. 2. The walls of the pharynx drawn to each side. 3, 3. The posterior nares, separated by the vomer. 4. The extremity of the Eustachian tube of one side. 5. The soft palate. 6. The posterior pillar of the soft palate. 7. Its anterior pillar; the tonsil is seen situated in the niche between the two pillars. 8. The root of the tongue, partly concealed by the uvula. 9. The epiglottis, overhanging (10) the cordiform opening of the larynx. 11. The posterior part of the larynx. 12. The opening into the oesophagus. 13. The external surface of the oesophagus. 14. The trachea.
above the posterior termination of the inferior turbinated bone, is the irregular depression in the mucous membrane, marking the entrance of the **Eustachian tube**. Beneath the posterior nares is the large opening into the **mouth**, partly veiled by the soft palate; and, beneath the root of the tongue, the cordiform opening of the larynx. The **oesophageal opening** is the lower constricted portion of the pharynx.

**Oesophagus.**—The **oesophagus** (**οίσθως**, to bear, **φαγέω**, to eat), is a slightly flexuous canal, inclining to the left in the neck, to the right in the upper part of the thorax,* and again to the left in its course through the posterior mediastinum; it commences at the termination of the pharynx, opposite the lower border of the cricoid cartilage and fifth cervical vertebra, and descends the neck behind and rather to the left of the trachea. It then passes behind the arch of the aorta, and along the posterior mediastinum, lying in front of the thoracic aorta, to the **oesophageal opening** in the diaphragm, where it enters the abdomen, and terminates at the **cardiac orifice** of the stomach at a point about opposite the tenth dorsal vertebra. The **oesophagus** is flattened and narrow in the cervical region, and cylindrical in the rest of its course; its largest diameter is met with near the lower part of its course.

**The Stomach.**

The stomach is an expansion of the alimentary canal, situated in the left hypochondriac, and extending into the epigastric region. It is directed somewhat obliquely from above downwards, from left to right, and from before backwards; and in the female, where the injurious system of tight-lacing has been pursued, is longer than in the male. On account of the peculiarity of its form, it is divided into a **greater** or **spleenic**, and a **lesser** or **pyloric** end; a **lesser curvature** above, and a **greater curvature** below; an anterior and a **posterior surface**; a **cardiac orifice**, and a **pyloric orifice**. The great end is not only of large size, but expands beyond the point of entrance of the **oesophagus**, and is embraced by the concave surface of the spleen. The pylorus is the small and contracted extremity of the organ; near its extremity is a small dilatation which was called by Willis the antrum of the pylorus. The two curvatures give attachment to the peritoneum; the upper curve to the lesser omentum, and the lower to the greater omentum. The anterior surface looks upwards and forwards, and is in relation with the diaphragm, which separates it from the viscera of the thorax and from the six lower ribs, with the left lobe of the liver, and in the epigastric region, with the abdominal parietes. The posterior surface looks downwards and backwards, and is in relation with the diaphragm, the pancreas, the third portion of the duodenum, the transverse meso colon, the left kidney, and left supra-renal capsule; this sur-

* Cruveilhier remarks that this inflexion explains the obstruction which a bougie sometimes meets with in its passage along the **oesophagus** opposite the first rib.
face forms the anterior boundary of that cul-de-sac of the peritoneum which is situated behind the lesser omentum and extends into the greater omentum.

**SMALL INTESTINES.**

The small intestine is about twenty-five feet in length, and is divisible into three portions, **duodenum**, **jejenum**, and **ileum**.

*Fig. 169.*

The **Duodenum** (called δωδεκάκτονον by Herophilus) is somewhat larger than the rest of the small intestines, and has received its name from being about equal in length to the breadth of twelve fingers. Commencing at the pylorus, it ascends obliquely backwards to the under surface of the liver; it next descends perpendicularly in front of the

* A vertical and longitudinal section of the stomach and duodenum, made in such a direction as to include the two orifices of the stomach. 1. The oesophagus; upon its internal surface the plicated arrangement of the cuticular epithelium is shown. 2. The cardiac orifice of the stomach, around which the fringed border of the cuticular epithelium is seen. 3. The great end of the stomach. 4. Its lesser or pyloric end. 5. The lesser curve. 6. The greater curve. 7. The dilatation at the lesser end of the stomach, which has received from Willis the name of antrum of the pylorus. This may be regarded as the rudiment of a second stomach. 8. The rugae of the stomach formed by the mucous membrane: their longitudinal direction is shown. 9. The pylorus. 10. The oblique portion of the duodenum. 11. The descending portion. 12. The pancreatic duct and the ductus communis choledochus close to their termination. 13. The papilla upon which the ducts open. 14. The transverse portion of the duodenum. 15. The commencement of the jejunum. In the interior of the duodenum and jejunum, the valvulæ conniventes are seen.
right kidney, and then passes nearly transversely across the third lumbar vertebra; terminating in the jejunum on the left side of the second lumbar vertebra, where it is crossed by the superior mesenteric artery and vein. The first or oblique portion of its course, between two and three inches, is completely enclosed by the peritoneum; it is in relation, above with the liver and neck of the gall-bladder; in front with the greater omentum and abdominal parietes; and behind with the right border of the lesser omentum and its vessels. The second or perpendicular portion is situated altogether behind the peritoneum; it is in relation by its anterior surface with the commencement of the arch of the colon; by its posterior surface with the concave margin of the right kidney, the inferior vena cava, and the ductus communis choledochus; by its right border with the ascending colon; and by its left border with the pancreas. The ductus communis choledochus and pancreatic duct open into the internal and posterior side of the perpendicular portion, a little below its middle. The third or transverse portion of the duodenum lies between the diverging layers of the transvers meso-colon, with which and with the stomach it is in relation in front; above it is in contact with the lower border of the pancreas, the superior mesenteric artery and vein being interposed; and behind it rests upon the inferior vena cava and aorta.

The Jejunum (jejunos, empty) is named from being generally found empty. It forms the upper two-fifths of the small intestine; commencing at the duodenum on the left side of the second lumbar vertebra, and terminating in the ileum. It is thicker to the touch than the rest of the intestine, and has a pinkish tinge from containing more mucous membrane than the ileum.

The Ileum (ulus, to twist, to convolute) includes the remaining three-fifths of the small intestine. It is somewhat smaller in calibre, thinner in texture, and paler than the jejunum; but there is no mark by which to distinguish the termination of the one or the commencement of the other. It terminates in the right iliac fossa, by opening at an obtuse angle into the colon.

The jejunum and ileum are surrounded above and at the sides by the colon; in front they are in relation with the omentum and abdominal parietes; they are retained in their position by the mesentery, which connects them with the posterior wall of the abdomen; and below they descend into the cavity of the pelvis. At about the lower third of the ileum a pouch-like process or diverticulum of the intestine is occasionally seen. This is a remnant of embryonic structure, and is formed by the obliteration of the vitelline duct at a short distance from the cylinder of the intestine.

LARGE INTESTINE.

The large intestine, about five feet in length, is sacculated in appearance, and is divided into the cæcum, colon, and rectum.

The Cæcum (cæcus, blind) is the blind pouch, or cul-de-sac, at the
commencement of the large intestine. It is situated in the right iliac fossa, and is retained in its place by the peritoneum, which passes over its anterior surface; its posterior surface is connected by loose areolar tissue with the iliac fascia. Attached to its extremity is the appendix vermiformis, a long worm-shaped tube, the rudiment of the lengthened cæcum found in all mammiferous animals except man and the higher quadruped. The appendix varies in length, from one to five or six inches; it is about equal in diameter to a goose-quill, and is connected with the posterior and left aspect of the cæcum near the extremity of the ileum. It is usually more or less coiled upon itself, and retained in that coil by a falceiform duplication of peritoneum. Its canal is extremely small, and the orifice by which it opens into the cæcum not unfrequently provided with an incomplete valve. Occasionally the peritoneum invests the cæcum so completely as to constitute a meso-cæcum, which permits of an unusual degree of movement in this portion of the intestine, and serves to explain the occurrence of hernia of the cæcum upon the right side. The cæcum is the most dilated portion of the large intestine.

The Colon is divided into ascending, transverse, and descending. The ascending colon passes upwards from the right iliac fossa, through the right lumbar region, to the under surface of the liver. It then bends inwards, and crosses the upper part of the umbilical region under the name of transverse colon, and on the left side descends (descending colon) through the left lumbar region to the left iliac fossa, where it makes a remarkable curve upon itself, which is called the sigmoid flexure.

The ascending colon, the most dilated portion of the large intestine, next to the cæcum, is retained in its position in the abdomen either by the peritoneum passing simply in front of it or by a narrow meso-colon. It is in relation in front with the small intestine and abdominal parietes; behind with the quadratus lumborum muscle and right kidney; internally with the small intestine and the perpendicular portion of the duodenum; and by its upper extremity with the under surface of the liver and gall-bladder. The transverse colon, the longest portion of the large intestine, forms a curve across the cavity of the abdomen, the convexity of which looks forwards and sometimes downwards. It is in relation by its upper surface with the liver, gall-bladder, stomach, and lower extremity of the spleen; by its lower surface with the small intestine; by its anterior surface with the anterior layers of the great omentum and the abdominal parietes; and by its posterior surface with the transverse meso-colon. The descending colon is smaller in calibre, and is situated more deeply than the ascending colon. Its relations are precisely similar. The sigmoid flexure is the narrowest part of the colon; it curves in the first place upwards and then downwards, and to one or the other side, and is retained in its place by a meso-colon. It is in relation in front with the small intestine and abdominal parietes; behind with the iliac fossa, and on either side with the small intestine.
The Rectum is the termination of the large intestine. It has received its name, not so much from the direction of its course, as from the straightness of its form in comparison with the colon. It descends, from opposite the left sacro-iliac symphysis, in front of the sacrum, forming a gentle curve to the right side, and then returning to the middle line; near the extremity of the coccyx it curves backwards to terminate at the anus at about an inch in front of the apex of that bone. The rectum, therefore, forms a double flexure in its course, the one being directed from side to side, the other from before backwards. It is smaller in calibre at its upper part than the sigmoid flexure, but becomes gradually larger as it descends, and its lower extremity, previously to its termination at the anus, forms a dilatation of considerable but variable magnitude.

With reference to its relations, the rectum is divided into three portions; the first, including half its length, extends to about the middle of the sacrum, is completely surrounded by peritoneum, and connected to the sacrum by means of the meso-rectum. It is in relation above with the left sacro-iliac symphysis, and below with the branches of the internal iliac artery, and with the sacral plexus of nerves; one or two convolutions of the small intestine are interposed between the front of the rectum and the bladder in the male; and between the rectum and the uterus with its appendages in the female. The second portion, about three inches in length, is closely attached to the surface of the sacrum, and covered by peritoneum only in front; it is in relation by its lower part with the base of the bladder, vesiculae seminales, and prostate gland, and in the female with the vagina. The third portion curves backwards from opposite the prostate gland to terminate at the anus; it is embraced by the levatores ani, and is about one inch and a half in length. It is separated from the membranous portion of the urethra by a triangular space; in the female this space intervenes between the vagina and the rectum, and constitutes by its base the perineum.

The Anus is situated at a little more than an inch in front of the extremity of the coccyx. The integument around it is covered with hairs, and is thrown into numerous radiated plaits which are obliterated during the passage of feces. The margin of the anus is provided with an abundance of sebaceous glands, and the epidermis may be seen terminating by a fringed and scalloped border, at a few lines above the extremity of the opening.

**STRUCTURE OF THE INTESTINAL CANAL.**

The pharynx has three coats; a mucous coat, a fibrous coat derived from the pharyngeal fascia, and a muscular layer. The oesophagus has but two coats, the mucous and muscular. The stomach and intestines have three, mucous and muscular, and an external serous investment, derived from the peritoneum.
MUCOUS COAT.—The mucous membrane of the mouth invests the whole internal surface of that cavity, and is reflected along the parotid, submaxillary, and sublingual ducts, into the corresponding glands. It terminates anteriorly upon the outer margin of the red border of the lips, and posteriorly is continuous with the mucous lining of the pharynx. The mucous membrane of the pharynx is continuous with the mucous lining of the Eustachian tubes, the nares, the mouth, and the larynx. In the oesophagus it is thick, very loosely connected with the muscular coat, and disposed in longitudinal plicae. In the stomach the mucous membrane is thin and vascular at the great extremity, and becomes thicker and lighter in colour towards the pyloric extremity. It is formed into plaits or rugæ, which are disposed for the most part in a longitudinal direction. The rugæ are most numerous towards the lesser end of the stomach; while around the cardiac orifice they assume a radiated arrangement. At the pylorus the mucous membrane forms a circular or spiral fold which constitutes a part of the apparatus of the pyloric valve. In the lower half of the duodenum, the whole length of the jejunum, and the upper part of the ileum, it forms valvular folds called valvula conniventes, which are several lines in breadth in the lower part of the duodenum and upper portion of the jejunum, and diminish gradually in size towards each extremity. These folds do not entirely surround the cylinder of the intestine, but extend for about one-half or three-fourths of its circumference. In the lower half of the ileum the mucous lining is without folds; hence the thinness of the coats of this intestine as compared with the jejunum and duodenum. At the termination of the ileum in the caecum, the mucous membrane forms two folds, which are strengthened by the muscular coat, and project into the caecum. These are the ilio-cecal valve (Valvula Bauhini). In the caecum and colon the mucous membrane is raised into crescentic folds, which correspond with the sharp edges of the sacculi; and, in the rectum, it forms three valvular folds, one of which is situated near the commencement of the intestine; the second, extending from the side of the tube, is placed opposite the middle of the sacrum; and the third, which is the largest and most constant, projects from the anterior wall of the intestine opposite the base of the bladder. Besides these folds, the membrane in the empty state of the intestine is thrown into longitudinal plaits, somewhat similar to those of the oesophagus; these have been named the columns of the rectum. The mucous membrane of the rectum is connected to the muscular coat by a very loose areolar tissue, as in the oesophagus.

Structure of Mucous Membrane.—This membrane is analogous to the cutaneous covering of the exterior of the body, and resembles that tissue very closely in its structure. It is composed of three layers, an epithelium, a proper mucous, and a fibrous layer.

* Mr. Houston, "On the Mucous Membrane of the Rectum." Dublin Hospital Reports, Vol. V.
The *Epithelium* is the epidermis of the mucous membrane. Throughout the pharynx and oesophagus it resembles the epidermis, both in appearance and character. It is continuous with the epidermis of the skin at the margin of the lips, and terminates by an irregular border at the cardiac orifice of the stomach. At the opposite extremity of the canal it terminates by a scalloped border just within the verge of the anus. In the mouth it is composed of laminae of cytoblasts, cells, and polygonal scales (fig. 160). Each cell and each scale possesses a central nucleus, and within the nucleus are one or more nucleus-corpuscles. According to Mr. Nasmyth,* the deepest lamina of the epithelium appears to consist of nuclei (cytoblasts) only; in the next the investing vesicle or cell is developed; the cells by degrees enlarge and become flattened, and in the superficial laminae are converted into thin scales. The nuclei, the cells, and the scales, are connected together by a glutinous fluid of the consistence of jelly, which contains an abundance of minute opaque granules. The scales of the superficial layer overlap each other by their margins. During the natural functions of the mucous membrane the superficial scales exfoliate continually and give place to the-deeper layers. In the stomach and intestines these bodies are pyriform in shape, and have a columnar arrangement, the apices being applied to the papillary surface of the membrane, and the bases forming by their approximation the free intestinal surface. Each column is provided with a central nucleus and nucleus-corpuscle, which gives to its middle a swollen appearance; and, from the transparency of its structure, the nucleus may be seen through the base of the column, when examined from the surface. Around the circular villi the columns, from being placed perpendicularly to the surface, have a radiated arrangement. The columnar epithelium is produced in the same manner with the laminated epithelium, in cytoblasts, cells, and columns, and the latter are continually thrown off to give place to successive layers.

The *Proper mucous, or Papillary layer* is analogous to the papillary layer of the skin, and, like it, is the secreting structure by which the epithelium is produced. Its surface presents several varieties of appearance when examined in different parts of its extent. In the stomach it forms polygonal cells, into the floor of which the gastric follicles open. In the small intestine it presents numerous minute, projecting papillae, called villi. The villi are of two kinds, **cylindrical** and **laminated**, and so abundant, as to give to the entire surface a beautiful velvety appearance. In the large intestine the surface is composed of a fine network of minute polygonal cells, more numerous than those of the stomach, but resembling them in receiving the secretion from numerous perpendicular follicles into their floors.

The *Fibrous layer* (sub-mucous, nervous) is the membrane of sup-

port to the mucous membrane, as is the corium to the papillary layer of the skin. It gives to the mucous membrane its strength and resistance, is but loosely connected with the mucous layer, but is firmly adherent to the muscular stratum, and is called, in the older works on anatomy, the "nervous coat."

**Glands.**—In the loose areolar tissue connecting the mucous with the fibrous layer, are situated the glands and follicles belonging to the mucous membrane: these are the—

- Pharyngeal glands,
- Esophageal glands,
- Gastric follicles,
- Duodenal glands (Brunner’s),
- Glandulae solitariae,
- Glandulae aggregatae (Peyer’s),
- Simple follicles (Lieberkühn’s).

The *Pharyngeal glands* are situated in considerable numbers beneath the mucous membrane of the pharynx, particularly around the posterior nares. Two of these glands, of larger size than the rest, and lobulated in structure, occupy the margin of the opening of the Eustachian tube.

The *Esophageal glands* are small lobulated bodies, situated in the sub-mucous tissue, and opening upon the surface of the oesophagus by a long excretory duct, which passes obliquely through the mucous membrane.

The *Gastric follicles* are long tubular follicular glands, situated perpendicularly side by side in every part of the mucous membrane of the stomach. At their terminations they are dilated into small lateral pouches, which give them a clustered appearance. This character is more clearly exhibited at the pyloric than at the cardiac end of the stomach. They are intended, very probably, for the secretion of the gastric fluid.

The *Duodenal*, or *Brunner’s* glands, are small flattened granular bodies, compared collectively by Von Brunn to a second pancreas. They resemble in structure the small salivary glands, so abundant beneath the mucous membrane of the mouth and lips; and, like them, they open upon the surface by minute excretory ducts. They are limited to the duodenum.

The *Solitary glands* are of two kinds, those of the small and those of the large intestine. The former are small circular patches, surrounded by a zone or wreath of simple follicles. When opened, they are seen to consist of a small flattened saccular cavity, containing a mucous secretion, but having no excretory duct. They are chiefly found in the lower part of the ileum. The solitary glands of the large intestine

are most abundant in the cæcum and appendix cæci; they are small circular projections, flattened upon the surface, and perforated in the centre by a minute excretory opening.

The Aggregate, or Peyer's* glands, are situated near the lower end of the ileum, and occupy that portion of the intestine which is opposite the attachment of the mesentery. To the naked eye they present the appearance of oval disks, covered with small irregular fissures; but with the aid of the microscope they are seen to be composed of numerous small circular patches, surrounded by simple follicles, like the solitary glands of the small intestine. Each patch corresponds with a flattened and closed sac, situated beneath the membrane, but having no excretory opening, and the interspace between the patches is occupied by flattened villi.

The Simple follicles, or follicles of Lieberkühn, are small pouches of the mucous layer, dispersed in immense numbers over every part of the mucous membrane.

Muscular coat.—The muscular coat of the pharynx consists of five pairs of muscles, which have been already described. The muscular coat of the rest of the alimentary canal is composed of two planes of fibres, an external longitudinal, and an internal circular.

The Oesophagus is very muscular; its longitudinal fibres are continuous above with the pharynx, and are attached in front to the vertical ridge on the posterior surface of the cricoid cartilage; the uppermost circular fibres are also attached to the cricoid cartilage. Below, both sets of fibres are continued upon the stomach. On the stomach the longitudinal fibres are most apparent along the lesser curve, and the circular at the smaller end. At the pylorus the latter are aggregated into a thick circular ring, which, with the spiral fold of mucous membrane found in this situation, constitutes the pyloric valve. At the great end of the stomach a new order of fibres is introduced, having for their object to strengthen and compress that extremity of the organ. They are directed more or less horizontally from the great end towards the lesser end, and are generally lost upon the sides of the stomach at about its middle; these are the oblique fibres.

The Small intestine is provided with both layers, equally distributed over the entire surface. At the termination of the ileum the circular fibres are continued into the two folds of the ilio-caecal valve, while the longitudinal fibres pass onwards to the large intestine. In the large intestine the longitudinal fibres commence at the appendix vermiformis and are collected into three bands, an anterior, broad; and two posterior and narrower bands. These bands are nearly one half shorter than the intestine, and give to it the sacculated appearance which is characteristic of the cæcum and colon. In the descending colon the posterior bands usually unite and form a single band. From this point the bands are continued downwards upon the sigmoid

* John Conrad Peyer, an anatomist of Schaffhausen, in Switzerland. His essay, "De Glandulis Intestinorum," was published in 1677.
flexure to the rectum, around which they spread out and form a thick and very muscular longitudinal layer. The circular fibres in the cæcum and colon are exceedingly thin; in the rectum they are thicker, and at its lower extremity they are aggregated into the thick muscular ring which is known as the internal sphincter ani.

**Serous coat.**—The pharynx and oesophagus have no covering of serous membrane. The alimentary canal within the abdomen has a serous layer, derived from the peritoneum.

The *Stomach* is completely surrounded by peritoneum excepting along the line of junction of the great and lesser omentum. The first or oblique portion of the duodenum is also completely included by the serous membrane with the exception of the points of attachment of the omenta. The descending portion has merely a partial covering on its anterior surface. The transverse portion is also behind the peritoneum, being situated between the two layers of the transverse meso-colon, and has but a partial covering. The rest of the small intestine is completely invested by it, excepting along the concave border to which the mesentery is attached. The cæcum is more or less invested by the peritoneum, the more frequent disposition being that in which the intestine is surrounded for three-fourths only of its circumference. The ascending and the descending colon are covered by the serous membrane only in front. The transverse colon is invested completely, with the exception of the lines of attachment of the greater omentum and transverse meso-colon. And the sigmoid flexure is entirely surrounded, with the exception of the part corresponding with the junction of the left meso-colon. The upper third of the rectum is completely enclosed by the peritoneum; the middle third has an anterior covering only, and the inferior third none whatsoever.

**Vessels and Nerves.**—The *Arteries* of the alimentary canal, as they supply the tube from above downwards, are the pterygo-palatine, ascending pharyngeal, superior thyroid, and inferior thyroid in the neck; oesophageal in the thorax; gastric, hepatic, splenic, superior and inferior mesenteric in the abdomen; and inferior mesenteric, iliac, and internal pudic in the pelvis. The *veins* from the abdominal alimentary canal unite to form the vena portae. The *lymphatics* and lacteals open into the thoracic duct.

The *Nerves* of the pharynx and oesophagus are derived from the glosso-pharyngeal, pneumogastric, and sympathetic. The nerves of the stomach are the pneumogastric and sympathetic branches from the solar plexus; and those of the intestinal canal are the superior and inferior mesenteric and hypogastric plexuses. The extremity of the rectum is supplied by the inferior sacral nerves from the spinal cord.
THE LIVER.

The liver is a conglomerate gland of large size, appended to the alimentary canal, and performing the double office of separating impurities from the venous blood of the chylo-poietic viscera previously to its return into the general venous circulation, and of secreting a fluid necessary to chylification, the bile. It is the largest organ in the body, weighing about four pounds, and measuring through its longest diameter about twelve inches. It is situated in the right hypochondriac region, and extends across the epigastrium into the left hypochondriac, frequently reaching by its left extremity to the upper end of the spleen. It is placed obliquely in the abdomen; its convex surface looking upwards and forwards, and the concave downwards and backwards. The anterior border is sharp and free and marked by a deep notch, and the posterior rounded and broad. It is in relation, superiorly and posteriorly with the diaphragm, and inferiorly with the stomach, ascending portion of the duodenum, transverse colon, right supra-renal capsule and right kidney, and corresponds by its free border with the lower margin of the ribs.

Ligaments.—The liver is retained in its place by five ligaments; four of which are formed by duplicatures of the peritoneum, and are

* The upper surface of the liver. 1. The right lobe. 2. The left lobe. 3. The anterior or free border. 4. The posterior or rounded border. 5. The broad ligament. 6. The round ligament. 7, 7. The two lateral ligaments. 8. The space left uncovered by the peritoneum, and surrounded by the coronary ligament. 9. The inferior vena cava. 10. The point of the lobus Spigelii. 3. The fundus of the gall-bladder seen projecting beyond the anterior border of the right lobe.
situated upon the convex surface of the organ; the fifth being a fibrous cord which passes through a fissure in its under surface, from the umbilicus to the inferior vena cava. They are the—

Longitudinal,
Two lateral,
Coronary,
Round.

The *Longitudinal ligament* (broad, ligamentum suspensory) is an antero-posterior fold of peritoneum, extending from the notch on the anterior margin of the liver to its posterior border. Between its two layers in the anterior and free margin is the round ligament.

The two *Lateral ligaments* are formed by the two layers of peritoneum, which pass from the under surface of the diaphragm to the posterior border of the liver; they correspond with its lateral lobes.

The *Coronary ligament* is formed by the separation of the two layers forming the lateral ligaments near their point of convergence. The posterior layer is continued unbroken from one lateral ligament into the other; but the anterior quits the posterior at each side, and is continuous with the corresponding layer of the longitudinal ligament. In this way a large oval surface on the posterior border of the liver is left uncovered by peritoneum, and is connected to the diaphragm by a dense areolar tissue. This space is formed principally by the right lateral ligament, and is pierced near its left extremity by the inferior vena cava, previously to the passage of that vessel through the tendinous opening in the diaphragm.

The *Round ligament* is a fibrous cord resulting from the obliteration of the umbilical vein, and situated between the two layers of peritoneum in the anterior border of the longitudinal ligament. It may be traced from the umbilicus, along the longitudinal fissure upon the under surface of the liver to the inferior vena cava to which it is connected.

**Fissures.**—The under surface of the liver is marked by five fissures which divide its surface into five compartments or lobes, two principal and three minor lobes; they are the—

**Fissures.**
Longitudinal fissure,
Fissure of the ductus venosus,
Transverse fissure,
Fissure for the gall bladder,
Fissure for the vena cava.

**Lobes.**
Right lobe,
Left lobe,
Lobus quadratus,
Lobus Spigelii,
Lobus caudatus.

The *Longitudinal fissure* is a deep groove running from the notch upon the anterior margin of the liver, to the posterior border of the organ. At about one-third from its posterior extremity it is joined by a short but deep fissure, the transverse, which meets it transversely from the under part of the right lobe.
The longitudinal fissure in front of this junction lodges the fibrous cord of the umbilical vein, and is generally crossed by a band of hepatic substance called the pons hepatis.

The *Fissure for the ductus venosus* is the shorter portion of the longitudinal fissure, extending from the junctional termination of the transverse fissure to the posterior border of the liver, and containing a small fibrous cord, the remains of the ductus venosus. This fissure is therefore but a part of the longitudinal fissure.

The *Transverse fissure* is the short and deep fissure, about two inches in length, through which the hepatic ducts, hepatic artery, and portal vein enter the liver. Hence this fissure was considered by the older anatomists as the gate (porta) of the liver; and the large vein entering the organ at this point, the portal vein. At their entrance into the transverse fissure the branches of the hepatic duct are the most anterior, next those of the artery, and most posteriorly the portal vein.

The *Fissure for the gall-bladder* is a shallow fossa extending forwards, parallel with the longitudinal fissure, from the right extremity of the...
transverse fissure to the free border of the liver, where it frequently forms a notch.

The Fissure for the vena cava is a deep and short fissure, occasionally a circular tunnel, which proceeds from a little behind the right extremity of the transverse fissure to the posterior border of the liver, and lodges in the inferior vena cava.

These five fissures taken collectively resemble an inverted Y, the base corresponding with the free margin of the liver, and the apex with its posterior border. Viewing them in this way, the two anterior branches represent the longitudinal fissure on the left, and the fissure for the gall-bladder on the right side; the two posterior, the fissure for the ductus venosus on the left, and the fissure for the vena cava on the right side, and the connecting bar the transverse fissure.

Lobes.—The Right lobe is four or six times larger than the left, from which it is separated on the concave surface by the longitudinal fissure, and on the convex by the longitudinal ligament. It is marked upon its under surface by the transverse fissure, and by the fissures for the gall-bladder and vena cava, and presents three depressions, one in front for the curve of the ascending colon, and two behind for the right supra-renal capsule, and kidney.

The Left lobe is small and flattened, convex upon its upper surface, and concave below, where it lies in contact with the anterior surface of the stomach. It is sometimes in contact by its extremity with the upper end of the spleen, and is in relation by its posterior border with the cardiac orifice of the stomach, and left pneumogastric nerve.

The Lobus quadratus is a quadrilateral lobe situated upon the under surface of the right lobe: it is bounded in front by the free border of the liver; behind by the transverse fissure; to the right by the gall-bladder; and to the left by the longitudinal fissure.

The Lobus Spigelii* is a small triangular lobe, also situated upon the under surface of the right lobe: it is bounded in front by the transverse fissure; and on the sides by the fissures for the ductus venosus and vena cava.

The Lobus caudatus is a small tail-like appendage to the lobus Spigelii, from which it runs outwards like a crest into the right lobe, and serves to separate the right extremity of the transverse fissure from the commencement of the fissure for the vena cava. In some livers this lobe is well marked, in others it is small and ill-defined.

Reverting to the comparison of the fissures with an inverted Y, it will be observed that the quadrilateral interval, in front of the transverse bar, represents the lobus quadratus; the triangular space behind the bar, the lobus Spigelii; and the apex of the letter, the point of union between the inferior vena cava, and the remains of the ductus venosus.

* Adrian Spigel, a Belgian physician, professor at Padua after Casserius in 1616. He assigned considerable importance to this little lobe, but it had been described by Sylvius full sixty years before his time.
Vessels and Nerves.—The vessels entering into the structure of the liver are also five in number; they are the

Hepatic artery,
Portal vein,
Hepatic veins,
Hepatic ducts,
Lymphatics.

The Hepatic artery, portal vein, and hepatic duct enter the liver at the transverse fissure, and ramify through portal canals to every part of the organ; so that their general direction is from below upwards, and from the centre towards the circumference.

The Hepatic veins commence at the circumference, and proceed from before backwards, to open into the vena cava, on the posterior border of the liver. Hence the branches of the two veins cross each other in their course.

The portal vein, hepatic artery, and hepatic duct are moreover enveloped in a loose areolar tissue, the capsule of Glisson, which permits them to contract upon themselves when emptied of their contents; the hepatic veins, on the contrary, are closely adherent by their parietes to the surface of the canals in which they run, and are unable to contract. By these characters the anatomist is enabled, in any section of the liver, to distinguish at once the most minute branch of the portal vein from the hepatic vein: the former will be found more or less collapsed, and always accompanied by an artery and duct, and the latter widely open and solitary.

The Lymphatics are described in the Chapter dedicated to those vessels.

The Nerves of the liver are derived from the systems both of animal and organic life; the former proceed from the right phrenic and pneumogastric nerves, and the latter from the hepatic plexus.

Structure and Minute Anatomy of the Liver.

The Liver is composed of lobules, of a connecting medium, called Glisson’s capsule, of the ramifications of the portal vein, hepatic duct, hepatic artery, hepatic veins, lymphatics, and nerves, and is enclosed and retained in its proper situation by the peritoneum.

The Lobules are small granular bodies, of about the size of a millet seed, of an irregular form, and presenting a number of rounded projecting processes upon their surface. When divided longitudinally, they have a foliated appearance, and transversely, a polygonal outline, with sharp or rounded angles, according to the smaller or greater quantity of Glisson’s capsule contained in the liver. Each lobule is divided upon its exterior into a base and a capsular surface. The base corresponds with one extremity of the lobule, is flattened, and
rests upon an hepatic vein, which is thence named sublobular. The capsular surface includes the rest of the periphery of the lobule, and has received its designation from being enclosed in an areolar capsule derived from the capsule of Glisson. In the centre of each lobule is a small vein, the intralobular, which is formed by the convergence of six or eight minute venules from the rounded processes of the periphery. The intralobular vein thus constituted takes its course through the centre of the longitudinal axis of the lobule, pierces the middle of its base, and opens into the sublobular vein. The periphery of the lobule, with the exception of its base, which is always closely attached to a sublobular vein, is connected by means of its areolar capsule with the capsular surfaces of surrounding lobules. The interval between the lobules is the interlobular fissure, and the angular interstices formed by the apposition of several lobules are the interlobular spaces.

The lobules of the centre of the liver are angular, and somewhat smaller than those of the surface, from the greater compression to which they are submitted. The superficial lobules are incomplete, and give to the surface of the organ the appearance, and all the advantages resulting from an examination of a transverse section.

"Each lobule is composed of a plexus of bilary ducts, of a venous plexus, formed by branches of the portal vein, of a branch (intralobular), of an hepatic vein, and of minute arteries; nerves and absorbents, it is to be presumed, also enter into their formation, but cannot be traced into them." "Examined with the microscope, a lobule is apparently composed of numerous minute bodies of a yellowish colour, and of various forms, connected with each other by vessels. These minute bodies are the acini of Malpighi." "If an uninjected lobule be ex-

amined and contrasted with an injected lobule, it will be found that
the acini of Malpighi in the former are identical with the injected
lobular biliary plexus in the latter, and the blood vessels in both will
be easily distinguished from the ducts.*

Glisson’s capsule is the areolar tissue which envelopes the hepatic
artery, portal vein, and hepatic duct, during their passage through
the right border of the lesser omentum, and which continues to sur-
round them to their ultimate distribution in the substance of the
lobules. It forms for each lobule a distinct capsule, which invests it
on all sides with the exception of its base, connects all the lobules
together, and constitutes the proper capsule of the entire organ. But
Glisson’s capsule is not mere areolar tissue; “it is to the liver what
the pia mater is to the brain; it is a cellulo-vascular membrane, in which
the vessels divide and subdivide to an extreme degree of minuteness;
which lines the portal canals, forming sheaths for the larger vessels
contained in them, and a web in which the smaller vessels ramify;
which enters the interlobular fissures, and with the vessels forms the
capsules of the lobules; and which finally enters the lobules, and with
the blood-vessels expands itself over the secreting biliary ducts.” Hence
arises a natural division of the capsule into three portions, a vaginal,
an interlobular, and a lobular portion.

The vaginal portion is that which invests the hepatic artery,
hepatic duct, and portal vein, in the portal canals; in the larger canals
it completely surrounds these vessels, but in the smaller is situated
only on that side which is occupied by the artery and duct. The inter-
lobular portion occupies the interlobular fissures and spaces, and the
lobular portion forms the supporting tissue to the substance of the
lobules.

The Portal vein, entering the liver at the transverse fissure, ramifies
through its structure in canals, which resemble, by their surfaces, the
external superficies of the liver, and are formed by the capsular sur-
faces of the lobules. These are the portal canals, and contain, besides
the portal vein with its ramifications, the artery and duct with their
branches.

In the larger canals, the vessels are separated from the parietes of
the cavity by a web of Glisson’s capsule; but, in the smaller, the
portal vein is in contact with the surface of the canal for about two-
thirds of its cylinder, the opposite third being in relation with the
artery and duct and their investing capsule. If, therefore, the portal
vein were laid open by a longitudinal incision in one of these smaller
canals, the coats being transparent, the outline of the lobules, bounded
by their interlobular fissures, would be as distinctly seen as upon the
external surface of the liver, and the smaller venous branches would
be observed entering the interlobular spaces.

The branches of the portal vein are, the vaginal, interlobular, and

* The Anatomy and Physiology of the Liver, by Mr. Kiernan, Phil. Trans.
1833, from which this, and the other paragraphs within inverted commas, on
the structure of the liver, are quoted.
lobular. The vaginal branches are those which, being given off in the portal canals, have to pass through the sheath (vagina) of Glisson's capsule, previously to entering the interlobular spaces. In this course they form an intricate plexus, the vaginal plexus, which, depending for its existence on the capsule of Glisson, necessarily surrounds the vessels, as does that capsule in the larger canals, and occupies the capsular side only in the smaller canals. The interlobular branches are given off from the vaginal portal plexus where it exists, and directly from the portal veins, in that part of the smaller canals where the coats of the vein are in contact with the walls of the canal. They then enter the interlobular spaces and divide into branches, which cover with their ramifications every part of the surface of the lobules with the exception of their bases, and those extremities of the superficial lobules which appear upon the surfaces of the liver. The interlobular veins communicate freely with each other, and with the corresponding veins of adjoining fissures, and establish a general portal anastomosis throughout the entire liver. The lobular branches are derived from the interlobular veins; they form a plexus within each lobule, and converge from the circumference towards the centre, where they terminate in the minute radicles of the intralobular vein. "This plexus, interposed between the interlobular portal veins and the intralobular hepatic vein, constitutes the venous part of the lobule, and may be called the lobular venous plexus." The irregular islets of the substance of the lobules, seen between the meshes of this plexus by means of the microscope, are the acini of Malpighi, and are portions of the lobular biliary plexus.

The portal vein returns the venous blood from the chylopoietic viscera, to be circulated through the lobules; it also receives the venous blood which results from the distribution of the hepatic artery.

The Hepatic duct, entering the liver at the transverse fissure, divides into branches, which ramify through the portal canals, with the portal vein and hepatic artery, to terminate in the substance of the lobules. Its branches, like those of the portal vein, are vaginal, interlobular, and lobular.

The Vaginal branches ramify through the capsule of Glisson, and form a vaginal biliary plexus, which, like the vaginal portal plexus, surrounds the vessels in the large canals, but is deficient on that side of the smaller canals near which the duct is placed. The branches given off by the vaginal biliary plexus are interlobular and lobular. The interlobular branches proceed from the vaginal biliary plexus where it exists, and directly from the hepatic duct on that side of the smaller canals against which the duct is placed. They enter the interlobular spaces, and ramify upon the capsular surface of the lobules, in the interlobular fissures, where they communicate freely with each other. The lobular ducts are derived chiefly from the interlobular; but to those lobules forming the walls of the portal canals, they pass directly from the vaginal plexus. They enter the lobule, and form a
plexus in its interior, the *lobular biliary plexus*, which constitutes the principal part of the substance of the lobule. The ducts terminate either in loops or in cæcal extremities.

The coats of the ducts are very vascular, and supplied with a number of mucous follicles, which are distributed irregularly in the larger, but are arranged in two parallel longitudinal rows in the smaller ducts.

The *Hepatic artery* enters the liver with the portal vein and hepatic duct, and ramifies with those vessels through the portal canals. Its branches are the vaginal, interlobular, and lobular. The *vaginal branches*, like those of the portal vein and hepatic duct, form a *vaginal plexus*, which exists throughout the whole extent of the portal canals, with the exception of that side of the smaller canals which corresponds with the artery. The *interlobular branches*, arising from the vaginal plexus and from the parietal side of the artery in the smaller canals, ramify through the interlobular fissures, and are principally distributed to the coats of the interlobular ducts.

"From the superficial interlobular fissures small arteries emerge, and ramify in the *proper capsule*, on the convex and concave surface of the liver, and in the ligaments. These are the *capsular arteries*." Where the capsule is well developed, "these vessels cover the surfaces of the liver with a beautiful plexus," and "anastomose with branches of the phrenic, internal mammary, and supra-renal arteries," and with the epigastric.

The *Lobular branches*, extremely minute and few in number, are the nutrient vessels of the lobules, and terminate in the lobular venous plexus.

All the venous blood resulting from the distribution of the hepatic artery, even that from the vasa vasorum of the hepatic veins, is returned into the portal vein.

The *Hepatic veins* commence in the substance of each lobule by minute venules, which receive the blood from the lobular venous plexus, and converge to form the intralobular vein. The *intralobular vein* passes through the central axis of the lobule, and through the middle of its base, to terminate in a sublobular vein; and the union of the sublobular veins constitutes the hepatic trunks, which terminate in the inferior vena cava. The hepatic venous system consists, therefore, of three sets of vessels; intralobular veins, sublobular veins, and hepatic trunks.

The *Sublobular veins* are contained in canals formed solely by the bases of the lobules, with which, from the absence of Glisson's capsule, they are in immediate contact. Their coats are thin and transparent; and, if they be laid open by a longitudinal incision, the bases of the lobules will be distinctly seen, separated by interlobular fissures, and perforated through the centre by the opening of the intralobular vein.

The *Hepatic trunks* are formed by the union of the sublobular veins; they are contained in canals (hepatic-venous) similar in structure to the portal canals, and lined by a prolongation of the proper capsule.
They proceed from before backwards, and terminate by two large openings, corresponding to the right and left lobe of the liver in the inferior vena cava.

**Summary.**—The liver has been shown to be composed of lobules; the lobules (excepting at their bases) are invested and connected together, the vessels supported, and the whole organ enclosed by Glisson's capsule; and they are so arranged, that the base of every lobule in the liver is in contact with an hepatic vein (sublobular).

The **Portal vein** distributes its numberless branches through portal canals, which are channeled through every part of the organ; it brings the returning blood from the chylopoietic viscera; it collects also the venous blood from the ultimate ramifications of the hepatic artery in the liver itself. It gives off branches in the canals, which are called **vaginal**, and form a venous **vaginal plexus**; these give off **interlobular branches**, and the latter enter the lobules and form **lobular venous plexuses**, from the blood circulating in which the bile is secreted.

The **Bile** in the lobule is received by a network of minute ducts, the **lobular biliary plexus**; it is conveyed from the lobule into the **interlobular ducts**; it is thence poured into the biliary **vaginal plexus** of the portal canals, and thence into the excreting ducts, by which it is carried to the duodenum and gall-bladder, after being mingled in its course with the mucous secretion from the numberless muciparous follicles in the walls of the ducts.

The **Hepatic artery** distributes branches through every portal canal; gives off **vaginal branches** which form a vaginal hepatic plexus, from which the **interlobular branches** arise, and these latter terminate ultimately in the lobular venous plexuses of the portal vein. The artery ramifies abundantly in the coats of the hepatic ducts, enabling them to provide their mucous secretion; and supplies the vasa vasorum of the portal and hepatic veins, and the nutrient vessels of the entire organ.

The **Hepatic veins** commence in the centre of each lobule by minute radicles, which collect the impure blood from the lobular venous plexus and convey it into the **intralobular veins**; these open into the **sublobular veins**, and the sublobular veins unite to form the large hepatic trunks by which the blood is conveyed into the vena cava.

**Physiological and pathological deductions.**—The physiological deduction arising out of this anatomical arrangement is, that the **bile is wholly secreted from venous blood**, and not from a mixed venous and arterial blood, as is stated by Müller; for although the portal vein receives its blood from two sources, viz., from the chylopoietic viscera and from the capillaries of the hepatic artery, yet the very fact of the blood of the latter vessel having passed through its capillaries into the portal vein, or in extremely small quantity into the capillary network of the lobular venous plexus, is sufficient to establish its venous character.

* For arguments on this contested question, see the article "Liver," in the "Cyclopaedia of Anatomy and Physiology," edited by Dr. Todd.
The pathological deductions depend upon the following facts:—
Each lobule is a perfect gland; of uniform structure, of uniform
colour, and possessing the same degree of vascularity throughout. It
is the seat of a double venous circulation, the vessels of the one
(hepatic) being situated in the centre of the lobule, and those of the
other (portal) in the circumference. Now the colour of the lobule, as
of the entire liver, depends chiefly upon the proportion of blood con-
tained within these two sets of vessels; and so long as the circulation
is natural the colour will be uniform. But the instant that any cause
is developed which shall interfere with the free circulation of either,
there will be an immediate diversity in the colour of the lobule.

Thus, if there be any impediment to the free circulation of the
venous blood through the heart or lungs, the circulation in the hepatic
veins will be retarded, and the sublobular and the intralobular veins
will become congested, giving rise to a more or less extensive redness
in the centre of each of the lobules, while the marginal or non-con-
gested portion presents a distinct border of a yellowish white, yellow,
or green colour, according to the quantity and quality of the bile it
may contain. "This is 'passive congestion' of the liver, the usual
and natural state of the organ after death;" and, as it commences
with the hepatic vein, it may be called the first stage of hepatic-venous
congestion.

But if the causes which produced this state of congestion continue,
or be from the beginning of a more active kind, the congestion will
extend through the lobular venous plexuses "into those branches of the
portal vein situated in the interlobular fissures, but not to those in the
spaces, which being larger, and giving origin to those in the fissures,
are the last to be congested." In this second stage the liver has a
mottled appearance, the non-congested substance is arranged in isolated,
circular and ramose patches, in the centres of which the spaces and
parts of the fissures are seen. This is an extended degree of hepatic-
venous congestion; it is "active congestion" of the liver, and very
commonly attends disease of the heart and lungs.

These are instances of partial congestion, but there is sometimes
general congestion of the organ. "In general congestion the whole
liver is of a red colour, but the central portions of the lobules are
usually of a deeper hue than the marginal portions."

GALL-BLADDER.

The Gall-bladder is the reservoir for the bile; it is a pyriform sac
situated in a fossa, upon the under surface of the right lobe of the liver,
and extending from the right extremity of the transverse fissure to its
free margin. It is divided into a body, fundus, and neck; the fundus
or broad extremity in the natural position of the liver is placed down-
wards, and frequently projects beyond the free margin of the liver,
while the neck, small and constricted, is directed upwards. This sac
is composed of three coats, serous, fibrous, and mucous. The serous coat is partial, is derived from the peritoneum, and covers that side only which is unattached to the liver. The middle or fibrous coat is a thin but strong fibrous layer, connected on one side to the liver, and on the other to the peritoneum. The internal or mucous coat is but loosely connected with the fibrous layer; it is everywhere raised into minute ruge, which give it a beautifully reticulated appearance, and forms at the neck of the sac a spiral valve. It is continuous through the hepatic duct with the mucous membrane lining all the ducts of the liver, and through the ductus communis choledochus, with the mucous membrane of the alimentary canal.

The Biliary ducts are, the ductus communis choledochus, the cystic, and the hepatic duct.

The Ductus communis choledochus (χωλή bilis, διχοματις recipio) is the common excretory duct of the liver and gall-bladder; it is about three inches in length, and commences upon the papilla, situated on the inner side of the cylinder of the perpendicular portion of the duodenum. Passing obliquely between the mucous and muscular coat, it ascends behind the duodenum, and through the right border of the lesser omen-
tum; and divides into two branches the cystic duct and the hepatic duct. It is constricted at its commencement in the duodenum, and
becomes dilated in its progress upwards.

The Cystic duct, about an inch in length, passes outwards to the neck of the gall-bladder, with which it is continuous.

The Hepatic duct continues onwards to the transverse fissure of the liver, and divides into two branches, which ramify through the portal canals to every part of the liver.

The coats of the hepatic ducts are an external or fibrous, and an in-
ternal or mucous. The external coat is composed of a contractile fibrous tissue, which is probably muscular; but its muscularity has not yet been demonstrated in the human subject. The mucous coat is continuous on the one hand with the lining membrane of the hepatic ducts and gall-bladder, and on the other with that of the duodenum.

Vessels and Nerves.—The gall-bladder is supplied with blood by the cystic artery, a branch of the hepatic. Its veins return their blood into the portal vein. The nerves are derived from the hepatic plexus.

THE PANCREAS.

The Pancreas is a long, flattened, conglomerate gland, analogous to the salivary glands. It is about six inches in length, and between three and four ounces in weight; is situated transversely across the posterior wall of the abdomen, behind the stomach, and resting upon the aorta, vena portæ, inferior vena cava, the origin of the superior mesenteric artery, and the left kidney and supra-renal capsule; oppo-
site the first and second lumbar vertebrae. It is divided into a body, a greater, and a smaller extremity; the great end or head is placed
towards the right, and is surrounded by the curve of the duodenum; the lesser end extends to the left as far as the spleen. The anterior surface of the body of the pancreas is covered by the ascending posterior layer of peritoneum, and is in relation with the stomach, the first portion of the duodenum and the commencement of the transverse arch of the colon. The posterior surface is grooved for the splenic vein, and tunneled by a complete canal for the superior mesenteric and portal vein, and for the superior mesenteric artery. The upper border presents a deep groove, sometimes a canal for the splenic artery and vein, and is in relation with the oblique portion of the duodenum, the lobus Spigelii, and celiac axis. And the lower border is separated from the transverse portion of the duodenum by the superior mesenteric artery and vein. Upon the posterior part of the head of the pancreas is a lobular fold of the gland which completes the canal of the superior mesenteric vessels, and is called the lesser pancreas.

In structure the pancreas is composed of reddish-yellow polygonal lobules; these consist of smaller lobules, and the latter are made up of the arborescent ramifications of minute ducts, terminating in cæcal pouches.

The pancreatic duct commences at the papilla upon the inner and posterior surface of the perpendicular portion of the duodenum by a small dilatation which is common to it and the ductus communis choledochus, and passing obliquely between the mucous and muscular coats, runs from right to left through the middle of the gland, lying nearer to its anterior than its posterior surface. At about the commencement of the apical third of its course it divides into two parallel terminal branches. It gives off numerous small branches, which are distributed through the lobules, and constitute with the latter the substance of the gland. The duct which receives the secretion from the lesser pancreas is called the ductus pancreaticus minor; it opens into the principal duct near the duodenum, and sometimes passes separately into that intestine. As a variety, two pancreatic ducts are occasionally met with.

Vessels and Nerves.—The arteries of the pancreas are branches of the splenic, hepatic, and superior mesenteric; the veins open into the splenic vein; the lymphatics terminate in the lumbar glands. The nerves are filaments of the splenic plexus.

THE SPLEEN.

The spleen is an oblong flattened organ of a dark-bluish red colour, situated in the left hypochondriac region. It is very variable in size and weight, spongy and vascular in texture and exceedingly friable. The external surface is convex, the internal slightly concave, indent-ed along the middle line, and pierced by several large and irregular openings for the entrance and exit of vessels; this is the hilus lienüs. The upper extremity is somewhat larger than the lower, and rounded; the inferior is flattened; the posterior border is obtuse, the anterior is
sharp, and marked by several notches. The spleen is in relation by its
external or \textit{convex} surface with the diaphragm, which separates it
from the ninth, tenth, and eleventh ribs,—by its \textit{concave} surface with
the great end of the stomach, the extremity of the pancreas, the
gastro-splenic omentum with its vessels, the left kidney and supra-
renal capsule, and the left crus of the diaphragm; by its \textit{upper end}
with the diaphragm, and sometimes with the extremity of the left
lobe of the liver, and by its \textit{lower end} with the left extremity of the trans-
verse arch of the colon. It is connected to the stomach by the gastro-
splenic omentum and by the vessels contained in that duplicature. A
second spleen (lien succenturiatus) is sometimes found appended to
one of the branches of the splenic artery, near the great end of the
stomach ; when it exists, it is round and of small size, rarely larger than
a hazel-nut. I have seen two, and even three of these bodies. The
spleen is invested by the peritoneum and by a \textit{tunica propria} of yellow
estic tissue, which enables it to yield to the greater or less distension
of its vessels. The elastic tunic forms sheaths for the vessels in their
ramifications through the organ, and from these sheaths small fibrous
bands are given off in all directions, which become attached to the in-
ternal surface of the elastic tunic, and constitute the areolar framework
of the spleen. The substance occupying the interspaces of this tissue
is soft, granular, and of a bright red colour; in animals it is interspersed
with small, white, soft corpuscles, (Malpighian bodies) which are
sometimes seen in man.

\textit{Vessels and Nerves.}—The \textit{Splenic artery} is of very large size in pro-
portion to the bulk of the spleen; it is a division of the coeliac axis.
The branches which enter the spleen are distributed to distinct sections
of the organ, and anastomose very sparingly with each other. The
\textit{veins} by their numerous dilatations constitute the principal part of the
bulk of the spleen; they pour their blood into the splenic vein, which
is one of the two great formative trunks of the portal vein. The \textit{lym-
phatics} are remarkable for their number and large size; they terminate
in the lumbar glands. The \textit{nerves} are the splenic plexus, derived
from the solar plexus.

\textbf{THE SUPRA-RENAL CAPSULES.}

The supra-renal capsules are two small yellowish and flattened
bodies surmounting the kidneys, and inclining inwards towards the
vertebral column. The right is somewhat three-cornered in shape,
the left semilunar; they are connected to the kidneys by the common
investing areolar tissue, and each capsule is marked upon its anterior
surface by a fissure which appears to divide it into two lobes. The
right supra-renal capsule is closely adherent to the posterior and under
surface of the liver, and the left lies in contact with the pancreas.
Both capsules rest upon the crura of the diaphragm on a level with
the tenth dorsal vertebra, and by their inner border are in relation
with the great splanchnic nerve, and semilunar ganglion. They are
larger in the fetus than in the adult, and appear to perform some office connected with embryonic life. The anatomy of these organs in the fetus will be found in the succeeding Chapter.

In structure they are composed of two substances, cortical and medullary. The cortical substance is of a yellowish colour, and consists of straight parallel fibres placed perpendicularly side by side. The medullary substance is generally of a dark-brown colour, double the quantity of the yellow substance, soft and spongy in texture, and contains within its centre the trunk of a large vein, the vena suprarenalis. It is the large size of this vein that gives to the fresh supra-renal capsule the appearance of a central cavity: the dark-coloured pulpy or fluid contents of the capsule, at a certain period after death, are produced by softening of the medullary substance. Dr. Nagel * has shown, by his injections and microscopic examinations, that the appearance of straight fibres in the cortical substance is caused by the direction of a plexus of capillary vessels. Of the numerous minute arteries, supplying the supra-renal capsule, he says, the greater number enter the cortical substance at every point of its surface, and, after proceeding for scarcely half a line, divide into a plexus of straight capillary vessels. Some few of the small arteries pierce the cortical layer, and give off several branches in the medullary substance, which proceed in different directions, and re-enter the cortical layer to divide into a capillary plexus in a similar manner with the preceding. From the capillary plexus, composing the cortical layer, the blood is received by numerous small veins which form a venous plexus in the medullary substance, and terminate at acute angles in the large central vein.

Vessels and Nerves.—The supra-renal arteries are derived from the aorta, from the renal, and from the phrenic arteries; they are remarkable for the innumerable minute twigs into which they divide previously to entering the capsule. The supra-renal vein collecting the blood from the medullary venous plexus, and receiving several branches which pierce the cortical layer, opens directly into the vena cava on the right side, and into the renal vein on the left.

The Lymphatics are large and very numerous; they terminate in the lumbar glands. The nerves are derived from the renal and from the phrenic plexus.

THE KIDNEYS.

The kidneys, the secreting organs of the urine, are situated in the lumbar regions behind the peritoneum, and on each side of the vertebral column, which they approach by their upper extremities. Each kidney is between four and five inches in length, about two inches and a half in breadth, somewhat more than one inch in thickness, and weighs between three and five ounces. The kidneys are usually en-

* Müller's Archiv. 1836.
closed in a quantity of fat; they rest upon the diaphragm, upon the anterior lamella of the transversalis muscle, which separates them from the quadratus lumborum, and upon the psoas magnus. The right kidney is somewhat lower than the left, from the position of the liver; it is in relation by its anterior surface with the liver and descending portion of the duodenum, which rest upon it, and is covered in by the ascending colon and by its flexure. The left kidney, higher than the right, is covered in front by the great end of the stomach, by the spleen, descending colon with its flexure, and by a portion of the small intestines. The anterior surface of the kidney is convex, while the posterior is flat; the superior extremity is in relation with the supra-renal capsule; the convex border is turned outwards towards the parietes of the abdomen; the concave border looks inwards towards the vertebral column, and is excavated by a deep fissure, the hilus renalis, in which are situated the vessels and nerves, and pelvis of the kidney; the renal vein being the most anterior, next the renal artery, and lastly the pelvis.

The kidney is dense and fragile in texture, and is invested by a proper fibrous capsule, which is easily torn from its surface. When divided by a longitudinal incision carried from the convex to the concave border, it is found to present in its interior two structures, an external or vascular (cortical), and an internal or tubular (medullary) substance. The tubular portion is formed of pale reddish-coloured conical masses, corresponding by their bases with the vascular structure, and by their apices with the hilus of the organ; these bodies are named cones (pyramids of Malpighi), and are from eight to fifteen in number. The vascular portion is composed of blood-vessels, and of the plexiform convolutions of uriniferous tubuli, and not only constitutes the surface of the kidney, but dips between the cones and surrounds them nearly to their apices.

If the surface of a section be examined more closely, the vascular

substance of the organ will be found to be studded with a multitude of minute, red, globular bodies; these are the Malpighian bodies or glomeruli. Each Malpighian body is about the $\frac{1}{100}$ of an inch in diameter, and is composed of a tuft of capillary vessels enclosed within the extremity of an uriniferous tube, so that the number of Malpighian bodies corresponds with the number of tubuli uriniferi. The presence of the capillary tuft necessarily produces a dilatation of the uriniferous tube; beyond the tuft the tube presents a constriction, and then assumes its proper diameter, namely, $\frac{1}{40}$ of an inch. Two-thirds of the diameter of the tube are occupied by a nucleated epithelium, which in the constricted portion just mentioned is provided with cilia, and in the dilated part or capsule which receives the capillary tuft is gradually lost. The capillary vessels of this vascular tuft are arranged in loops, closely packed together, without any bond of connecting tissue, and are derived from a small artery, which, after piercing the capsule, immediately divides in a radiated manner into several branches. From the interior of this little vascular ball a vein proceeds, smaller than the corresponding artery, and pierces the capsule close by the artery, to communicate with the efferent vessels of other Malpighian bodies and constitute a venous plexus.*

The Cones or pyramids are composed of minute straight tubuli uriniferi of about the diameter of a fine hair; they divide into parallel branches in their course, and terminate by minute openings upon the apex or papilla of each cone. The papillae are invested by mucous membrane, which is continuous with the tubuli, and forms a cup-like pouch, the calyx, around each papilla. The calices communicate with a common cavity of larger size, situated at each extremity, and in the middle of the organ; and these three cavities, the infundibula, constitute by their union the large membranous sac, which occupies the hilus renalis, the pelvis of the kidney.

The kidney in the embryo and foetus consists of lobules. See the anatomy of the foetus in the succeeding Chapter.

The Ureter (σύρων, urine, τρύγων, to keep), the excretory duct of the kidney, is a membranous tube of about the diameter of a goose-quill, and nearly eighteen inches in length; it is continuous superiorly with the pelvis of the kidney, and is constricted inferiorly, where it lies in an oblique direction between the muscular and mucous coats of the base of the bladder, and opens upon its mucous surface. Lying along the posterior wall of the abdomen, it is situated behind the peritoneum, and is crossed by the spermatic vessels; in its course downwards it rests upon the anterior surface of the psoas, and crosses the common iliac artery and vein, and then the external iliac vessels. Within the pelvis it crosses the umbilical artery and the vas deferens in the male, and the upper part of the vagina in the female. There are sometimes two ureters to one kidney. The ureter, the pelvis, the infundibula,

* For this account I am indebted to the excellent paper of Mr. Bowman, "On the Structure and Use of the Malpighian Bodies of the Kidney," &c. published in the Philosophical Transactions for 1842.
and the calices are composed of two coats, an external or fibrous coat, the tunica propria; and an internal mucous coat, which is continuous with the mucous membrane of the bladder inferiorly, and with the tubuli uriniferi above.

Vessels and Nerves.—The renal artery is derived from the aorta; it divides into several large branches before entering the hilus, and within the organ ramifies in an arborescent manner, terminating in nutrient twigs, and in the small efferent vessels of the corpora Malpighiana. In the Malpighian bodies the efferent vessels divide into several primary twigs, which subdivide into capillaries, and the capillaries, after forming loops, converge to the efferent vein, which is generally smaller than the corresponding artery. The efferent veins proceed to and form a capillary venous plexus, which surrounds the tortuous tubuli uriniferi, and from this venous plexus the blood is conveyed by converging branches into the renal vein.

"Thus," remarks Mr. Bowman, "there are in the kidney two perfectly distinct systems of capillary vessels, through both of which the blood passes in its course from the arteries into the veins: the first, that inserted into the dilated extremities of the uriniferous tubes and in immediate connection with the arteries; the second, that enveloping the convolutions of the tubes and communicating directly with the veins. The efferent vessels of the Malpighian bodies, that carry the blood between these two systems may collectively be termed the portal system of the kidney." The inferences drawn by Mr. Bowman from his investigations are peculiarly interesting; they are: that the capillary tufts of the Malpighian bodies are the part of the kidney specially acted on by diuretics; that they are the medium by which water, certain salts, and other substances pass out of the system; that they are, moreover, the means of escape of certain morbid products, such as sugar, albumen, and the red particles of the blood. Respecting the capillary venous plexus, we have proof that the principal proximate constituents of urine, such as, urea, lithic acid, &c. are, like the bile, derived from venous (portal) blood.

* Plan of the renal circulation; copied from Mr. Bowman's paper. a. A branch of the renal artery giving off several Malpighian twigs. 1. An efferent twig to the capillary tuft contained in the Malpighian body, m; from the Malpighian body the uriniferous tube is seen taking its tortuous course to 3. 2, 2. Efferent veins; that which proceeds from the Malpighian body is seen to be smaller than the corresponding artery. p, p. The capillary venous plexus, ramifications upon the uriniferous tube. This plexus receives its blood from the efferent veins, 2, 2, and transmits it to the branch of the renal vein, v.
The Veins terminate in the vena cava by a single large trunk on each side; the left renal vein receiving the left spermatic vein. Injections thrown into the renal artery and returning by the vein, generally make their way into those vessels by rupture; and when the injection returns by the tubuli uriniferi, it results from the bursting of the capillary tufts of the Malpighian bodies. The lymphatic vessels terminate in the lumbar glands.

The Nerves are derived from the renal plexus, which is formed partly by the solar plexus, and partly by the lesser splanchnic nerve. The renal plexus gives branches to the spermatic plexus, and branches which accompany the ureters: hence the morbid sympathies which exist between the kidney, the ureter, and the testicle: and by the communications with the solar plexus, with the stomach and diaphragm, and indeed with the whole system.

PELVIS.

The cavity of the pelvis is that portion of the great abdominal cavity which is included within the bones of the pelvis, below the level of the linea-ilio-pectinea and the promontory of the sacrum. It is bounded by the cavity of the abdomen above, and by the perineum below; its internal parietes are formed in front, below, and at the sides, by the peritoneum, pelvic fascia, levatores ani muscles, obturator fasciae and muscles; and behind, by the sacrum, and sacral plexus of nerves.

The Viscera of the pelvis in the male are the urinary bladder, the prostate gland, vesiculae seminales, and the rectum.

BLADDER.

The Bladder is an oblong membranous viscus of an ovoid shape, situated behind the os pubis and in front of the rectum. It is larger in its vertical diameter than from side to side; and its long axis is directed from above, obliquely downwards and backwards. It is divided into body, fundus, base, and neck. The body comprehends the middle zone of the organ; the fundus, its upper segment; the base, the lower broad extremity, which rests upon the rectum; and the neck the narrow constricted portion which is applied against the prostate gland.

This organ is retained in its place by ligaments which are divided into true and false; the true ligaments are seven in number, two anterior, two lateral, two umbilical, and the urachus; the false ligaments are folds of the peritoneum, and are four in number, two anterior and two posterior. The anterior ligaments are formed by the pelvic fascia, which passes from the inner surface of the os pubis, on each side of the symphysis, to the front of the bladder. The lateral ligaments are formed by the reflexion of the pelvic fascia from the levatores ani
muscles, upon the sides of the base of the bladder. The **umbilical ligaments** are the fibrous cords which result from the obliteration of the umbilical arteries of the foetus; they pass forwards on each side of the fundus of the bladder, and ascend beneath the peritoneum to the umbilicus. The **urachus** is a small fibrous cord formed by the obliteration of a tubular canal existing in the embryo: it is attached to the apex of the

BLADDER.—LIGAMENTS.

bladder, and thence ascends to the umbilicus. The *false ligaments* are folds of peritoneum; the two lateral correspond with the passage of the vasa deferentia from the sides of the bladder to the internal abdominal rings, and the two posterior with the course of the umbilical arteries, to the fundus of the organ.

The bladder is composed of three coats, an external or serous coat, a muscular, and a mucous coat. The *serous coat* is partial, and derived from the peritoneum, which invests the posterior surface and sides of the bladder, from about opposite the point of termination of the two ureters to its summit, whence it is guided to the anterior wall of the abdomen by the umbilical ligaments and urachus. The *muscular coat* consists of two layers, an external layer composed of longitudinal fibres, the detrusor urinæ; and an internal layer of oblique and transverse fibres irregularly distributed. The anterior longitudinal fibres commence by four tendons (the tendons of the bladder, or of the detrusor urinæ), two superior from the osa pubis, and two inferior from the rami of the ischia on each side, and spread out as they ascend upon the anterior surface of the bladder to its fundus; they then converge upon the posterior surface of the organ, and descend to its neck, where they are inserted into the isthmus of the prostate gland, and into a ring of muscular tissue, which surrounds the commencement of the prostatic portion of the urethra. Some of the anterior fibres are also attached to this ring. The lateral fibres commence at the prostate gland and the muscular ring of the urethra on one side, and spread out as they ascend upon the side of the bladder to descend upon the opposite side, and be inserted into the prostate and opposite segment of the same ring. Two bands of oblique fibres are described by Sir Charles Bell, as originating at the terminations of the ureters, and converging to the neck of the bladder; the existence of these muscles is not well established. The fibres corresponding with the trigonum vesicæ are transverse.

It has been shown by Mr. Guthrie,* that there are no fibres at the neck of the bladder capable of forming a sphincter vesicæ; but Mr. Lane† has described a fasciculus of muscular fibres which surround the commencement of the urethra, and perform such an office. These fibres form a narrow bundle above the urethra, but spread out below behind the prostate gland: they are brought into view by dissecting off the mucous membrane from around the orifice of the urethra.

Sir Astley Cooper has described around the urethra within the prostate gland, a ring of elastic tissue, or rather, according to Mr. Lane, of muscular fibres, which has for its object the closure of the urethra against the involuntary passage of the urine. It is into this ring that the longitudinal fibres of the detrusor urinæ are inserted, so that this muscle taking a fixed point at the os pubis will not only compress the bladder, and thereby tend to force its contents along the

---

* "On the Anatomy and Diseases of the Neck of the Bladder and of the Urethra"
† *Lancet*, vol. i. 1842-43, p. 670.
urethra; but will at the same time, by means of its attachment to the
ring dilate the entrance of the urethra, and afford a free egress to the
contents of the bladder.

The Mucous coat is thin and smooth, and exactly moulded upon the
muscular coat, to which it is connected by a somewhat thick layer of
submucous tissue, called by some anatomists the nervous coat; its
papillae are very minute, and there is scarcely a trace of mucous
follicles. This mucous membrane is continuous through the ureters
with the lining membrane of the uriniferous ducts and through the
urethra, with that of the prostatic ducts, tubuli seminiferi, and Cow-
per's glands.

Upon the internal surface of the base of the bladder is a triangular
smooth plane of a paler colour than the rest of the mucous membrane;
the trigonum vesicae, or trigone vesicale. This is the most sensitive
part of the bladder, and the pressure of calculi upon it gives rise to
great suffering. It is bounded on each side by the raised ridge,
corresponding with the muscles of the ureters, at each posterior angle
by the openings of the ureters, and in front by a slight elevation of
the mucous membrane at the entrance of the urethra, called uvula
vesicae.

The external surface of the base of the bladder corresponding with
the trigonum, is also triangular, and is separated from the rectum
merely by a thin layer of fibrous membrane, the recto-vesical fascia.
It is bounded behind by the recto-vesical fold of peritoneum; and on
each side by the vas deferens and vesicula seminalis, which converge
almost to a point at the base of the prostate gland. It is through
this space that the opening is made in the recto-vesical operation for
puncture of the bladder.

The prostate gland (προστάτημα præponere) is situated in front of the
neck of the bladder behind the deep perineal fascia and upon the
rectum, through which it may be felt with the finger. It surrounds
the commencement of the urethra for a little more than an inch of its
extent, and resembles a Spanish chestnut both in size and form; the
base being directed backwards towards the neck of the bladder, the
apex forwards, and the convex side towards the rectum. It is re-
tained firmly in its position by the two superior, and two inferior
tendons of the bladder, by the attachments of the pelvic fascia, and by
a process of the internal layer of the deep perineal fascia, which forms
a sheath around the membranous urethra, and is inserted into the
apex of the gland. It consists of three lobes, two lateral and a middle
lobe or isthmus; the lateral lobes are distinguished by an indentation
upon the base of the gland, and by a slight furrow upon its upper and
lower surface. The third lobe or isthmus is a small transverse band
which passes between the two lateral lobes at the base of the organ.
VESICULÆ SEMINALÆ.

In structure the prostate gland is composed of ramified ducts, terminating in lobules of follicular pouches, which are so closely compressed as to give to a thin section of the gland a cellular appearance beneath the microscope. It is pale in colour and hard in texture, splits easily in the course of its ducts, and is surrounded by a plexus of veins which are enclosed by the strong fibrous membrane with which it is invested. Its secretion is poured into the prostatic portion of the urethra by fifteen or twenty excretory ducts. The urethra in passing through the prostate lies one-third nearer to its upper than its lower surface.

VESICULÆ SEMINALÆ.

Upon the under surface of the base of the bladder, and converging towards the base of the prostate gland, are two lobulated and somewhat pyriform bodies, about two inches in length, the vesiculae seminales. Their upper surface is in contact with the base of the bladder; the under side rests upon the rectum, separated only by the recto-vesical fascia; the larger extremities are directed backwards and outwards, and the smaller ends almost meet at the base of the prostate. They enclose between them a triangular space, which is bounded posteriorly by the recto-vesical fold of peritoneum, and which corresponds with the trigonum vesicæ on the interior of the bladder. Each vesicula is formed by the convolutions of a single tube, which gives off several irregular cæcal branches. It is enclosed in a dense fibrous membrane, derived from the pelvic fascia, and is constricted beneath the isthmus of the prostate gland into a small excretory duct. The

* The posterior aspect of the male bladder; the serous covering is removed in order to shew the muscular coat. 1. The body of the bladder. 2. Its fundus. 3. Its inferior fundus or base. 4. The urachus. 5, 5. The ureters. 6, 6. The vasa deferentia. 7, 7. The vesiculae seminales. The triangular area, bounded by the vasa deferentia and vesiculae seminales on either side, a dotted line above, and the numeral 3 below, is the space corresponding with the trigonum vesicæ. It is this part of the bladder which is pierced, in puncturing the bladder through the rectum. The dotted line forming the base of this triangular area marks the extent of the recto-vesical fold of the peritoneum.
vas deferens, somewhat enlarged and convoluted, lies along the inner border of each vesicula, and is included in its fibrous investment. It communicates with the duct of the vesicula, beneath the isthmus of the prostate, and forms the ejaculatory duct. The ejaculatory duct is about three quarters of an inch in length, and running forwards, first between the base of the prostate and the isthmus, and then through the tissue of the veru montanum, opens upon the mucous membrane of the urethra, near its fellow of the opposite side, at the anterior extremity of that process.

MALE ORGANS OF GENERATION.

The organs of generation in the male are, the penis and the testes, with their appendages.

The Penis is divided into a body, root, and extremity. The body is surrounded by a thin integument, which is remarkable for the looseness of its areolar connexion with the deeper parts of the organ, and for containing no adipose tissue. The root is broad, and firmly adherent to the rami of the os pubis and ischium by means of two strong processes, the crura, and is connected to the symphysis pubis by a fibrous membrane, the ligamentum suspensorium. The extremity, or glans penis resembles an obtuse cone, somewhat compressed from above downwards, and of a deeper red colour than the surrounding skin. At its apex is a small vertical slit, the meatus urinarius, which is bounded by two more or less protuberant labia; and, extending backwards from the meatus, is a depressed raphé, to which is attached a loose fold of mucous membrane, the frænum præputii. The base of the glans is marked by a projecting collar, the corona glandis, upon which are seen a number of small papillary elevations, formed by the aggregation of minute sebaceous glands, the glandulae Tysoni (odoriferæ). Behind the corona is a deep fossa, bounded by a circular fold of integument, the praeputium, which, in the quiescent state of the organ, may be drawn over the glans, but, in its distended state, is obliterated, and serves to facilitate its enlargement. The internal surface of the prepuce is lined by mucous membrane, covered by a thin cuticle; this membrane, upon reaching the base of the glans, is reflected over the glans penis, and, at the meatus urinarius, becomes continuous with the mucous lining of the urethra.

The penis is composed of the corpus cavernosum and corpus spongiosum, and contains in its interior the longest portion of the urethra.

* It has been customary hitherto, in works on anatomy, to describe the course of excretory ducts as proceeding from the gland, and passing thence to the point at which the secretion is poured out. In the description of the vas deferens, with its connexion with the duct of the vesicula seminalis, I have adopted this plan, that I might not too far depart from established habit. But as it is more correct and consistent with the present state of science to consider the gland as a development of the duct, I have pursued the latter principle in the description of most of the other glandular organs of the body.
The Corpus cavernosum is distinguished into two lateral portions (corpora cavernosa), by an imperfect septum and by a superior and inferior groove, and is divided posteriorly into two crura. It is firmly adherent, by means of its crura, to the rami of the ossa pubis and ischia. It forms, anteriorly, a single rounded extremity, which is received into a fossa in the base of the glans penis; the superior groove lodges the dorsal vessels of the organ, and the inferior receives the corpus spongiosum. Its fibrous tunic is thick, elastic, and extremely firm, and sends a number of fibrous bands and cords (trabeculae) inwards from its inferior groove, which cross its interior in a radiating direction, and are inserted into the inner walls of the tunic. These trabeculae are most abundant on the middle line, where they are ranged vertically, side by side, somewhat like the teeth of a comb, and constitute the imperfect partition of the corpus cavernosum, called septum pectiniforme. This septum is more complete at its posterior than towards its anterior part.

The tunic of the corpus cavernosum consists of strong longitudinal fibrous fasciculi, closely interwoven with each other. Its internal structure is composed of erectile tissue.

The Corpus spongiosum is situated along the under surface of the corpus cavernosum, in its inferior groove. It commences by its posterior extremity between and beneath the crura penis, where it forms a considerable enlargement, the bulb, and terminates anteriorly by another expansion, the glans penis. Its middle portion, or body, is nearly cylindrical, and tapers gradually from its posterior towards its anterior extremity. The bulb is adherent to the deep perineal fascia by means of the tubular prolongation of the anterior layer, which surrounds the membranous portion of the urethra; in the rest of its extent the corpus spongiosum is attached to the corpus cavernosum by areolar tissue, and by veins which wind around that body to reach the dorsal vein. It is composed of erectile tissue, enclosed by a dense fibrous layer, much thinner than that of the corpus cavernosum, and contains in its interior the spongy portion of the urethra, which lies nearer its upper than its lower wall.

Erectile tissue is a peculiar cellulo-vascular structure, entering in considerable proportion into the composition of the organs of generation. It consists essentially of a plexus of veins so closely convoluted and interwoven with each other, as to give rise to a cellular appearance when examined upon the surface of a section. The veins forming this plexus are smaller in the glans penis, corpus spongiosum, and circumference of the corpus cavernosum, than in the central part of the latter, where they are large and dilated. They have no other coat than the internal lining prolonged from the neighbouring veins; and the interstices of the plexus are occupied by a peculiar reddish fibrous tissue. They receive their blood from the capillaries of the arteries in the same manner with veins generally, and not by means of vessels having a peculiar form and distribution, as described by Müller. The helicine arteries of that physiologist have no existence.
Vessels and Nerves.—The arteries of the penis are derived from the internal pudic; they are, the arteries of the bulb, arteries of the corpus cavernosum, and dorsales penis. Its veins are superficial and deep. The deep veins run by the side of the deep arteries, and terminate in the internal pudic veins. The superficial veins escape in considerable number from the base of the glans, and converge on the dorsum penis, to form a large dorsal vein, which receives other veins from the corpus cavernosum and spongiosum in its course, and passes backwards between two layers of the ligamentum suspensorium, and through the deep fascia beneath the arch of the os pubis, to terminate in the prostatic and vesical plexuses.

The Lymphatics terminate in the inguinal glands. The nerves are derived from the internal pudic nerve, from the sacral plexus, and, as shewn by Professor Müller in his beautiful monograph, from the hypogastric plexus.

URETHRA.

The urethra is the membranous canal extending from the neck of the bladder to the meatus urinarius. It is curved in its course, and is composed of two layers, a mucous coat and an elastic fibrous coat. The mucous coat is thin and smooth; it is continuous, internally, with the mucous membrane of the bladder; externally, with the investing membrane of the glans; and at certain points of its extent, with the lining membrane of the numerous ducts which open into the urethra, namely, those of Cowper's glands, the prostate gland, vasa deferentia, and vesiculæ seminales. The elastic fibrous coat varies in thickness in the different parts of the course of the urethra: it is thick in the prostate gland, forms a firm investment for the membranous portion of the canal, and is thin in the spongy portion, where it serves as a bond of connexion between the mucous membrane and the corpus spongiosum. The urethra is about nine inches in length, and is divided into a prostatic, membranous, and spongy portion.

The Prostatic portion, a little more than an inch in length, is situated in the prostate gland, about one-third nearer its upper than its lower surface, and extending from its base to its apex. Upon its lower circumference or floor is a longitudinal fold of mucous membrane, the veru montanum, or caput gallinaginis, and on each side of the veru, a depressed fossa, the prostatic sinus, in which are seen the numerous openings of the prostatic ducts. At the anterior extremity of the veru montanum are the openings of the two ejaculatory ducts, and between them a third opening, which leads backwards into a small cæcal sac, the sinus peculiaris. The prostatic portion of the urethra, when distended, is the most dilated part of the canal; but, excepting during the passage of urine, is completely closed by means of a ring of muscular tissue which encircles the urethra as far as the anterior extremity of the veru montanum. In the contracted state of the urethra, the veru montanum acts as a valve, being pressed upwards against the upper
MEMBRANOUS URETHRA.

wall of the canal; but, during the action of the detrusor muscle of the bladder, the whole ring is expanded by the longitudinal muscular fibres which are inserted into it; and the veru is especially drawn downwards by two delicate tendons, which have been traced by

A slight ridge, formed by the muscle of the ureter, and extending from the termination of the ureter to the commencement of the urethra. This ridge forms the lateral boundary of the trigonum vesicae. 5. The commencement of the urethra; the elevation of mucous membrane immediately behind the figure is the uvula vesice. The constriction of the bladder at this point is the neck of the bladder. 6. The prostatic portion of the urethra. 7. The prostate gland; the difference of thickness of the gland, above and below the urethra, is shewn. 8. The isthmus, or third lobe of the prostate; immediately beneath which the ejaculatory duct is seen passing. 9. The right vesicula seminalis; the vas deferens is seen to be cut short off, close to its junction with the ejaculatory duct. 10. The membranous portion of the urethra. 11. Cowper's gland of the right side, with its duct. 12. The bulbous portion of the urethra; throughout the whole length of the urethra of the corpus spongiosum, numerous lacunae are seen. 13. The fossa navicularis. 14. The corpus cavernosum, cut somewhat obliquely to the right side, near its lower part. The character of the venous-cellular texture is well shewn. 15. The right crus penis. 16. Near the upper part of the corpus cavernosum, the section has fallen a little to the left of the middle line; a portion of the septum pectiniforme is consequently seen. This figure also indicates the thickness of the fibrous investment of the corpus cavernosum, and its abrupt termination at the base of (17) the glans penis. 18. The lower segment of the glans. 19. The meatus urinarius. 20. The corpus spongiosum. 21. The bulb of the corpus spongiosum.
Mr. Tyrrell, from the posterior fibres of the detrusor into the tissue of this process.

The Membranous portion, the narrowest part of the canal, is somewhat less than an inch in length. It is situated between the two layers of the deep perineal fascia, and is surrounded by the fan-like expansions of the upper and lower segments of the compressor urethrae muscle which meet at the raphe along its upper and lower surface. It is continuous posteriorly with the prostatic urethra, and anteriorly with the spongy portion of the canal. Its coverings are the mucous membrane, elastic fibrous layer, compressor urethrae muscle, and a partial sheath from the deep perineal fascia.

The Spongy portion forms the rest of the extent of the canal, and is lodged in the corpus spongiosum from its commencement at the deep perineal fascia to the meatus urinarius. It is narrowest in the body, and becomes dilated at either extremity, posteriorly in the bulb, where it is named the bulbous portion, and anteriorly in the glans penis, where it forms the fossa navicularis. The meatus urinarius is the most constricted part of the canal; so that a catheter, which will enter that opening, may be passed freely through the whole extent of a normal urethra. Opening into the bulbous portion are two small excretory ducts about three-quarters of an inch in length, which may be traced backwards, between the coats of the urethra and the bulb, to the interval between the two layers of the deep perineal fascia, where they ramify in two small lobulated and somewhat compressed glands of about the size of peas. These are Cowper's glands; they are situated immediately beneath the membranous portion of the urethra, and are enclosed by the lower segment of the compressor urethrae muscle so as to be subject to muscular compression. Upon the whole of the internal surface of the spongy portion of the urethra, particularly along its upper wall, are numerous small openings or lacunae, which are the apertures of mucous glands situated in the submucous areolar tissue. The openings of these lacunae are directed forwards, and are liable occasionally to intercept the point of a small catheter in its passage into the bladder. At about an inch and a half from the opening of the meatus one of these lacunae is generally found much larger than the rest, and is named the lacuna magna. In a preparation of this lacuna, made by Sir Astley Cooper, the extremity of the canal presents several large primary ramifications.

TESTES.

The testes are two small glandular organs suspended from the abdomen by the spermatic cords, and enclosed in an external tegumentary covering, the scrotum.

The Scrotum is distinguished into two lateral halves or hemispheres by a raphe, which is continued anteriorly along the under surface of the penis, and posteriorly along the middle line of the perineum to
the annus. Of these two lateral portions the left is somewhat longer than the right, and corresponds with the greater length of the spermatic cord on the left side.

The scrotum is composed of two layers, the integument, and a proper covering, the dartos; the integument is extremely thin, transparent, and abundant, and beset by a number of hairs which issue obliquely from the skin, and have prominent roots. The dartos is a thin layer of contractile fibrous tissue, intermediate in properties between muscular fibre and elastic tissue; it forms the proper tunic of the scrotum, and sends inwards a distinct septum (septum scroti), which divides it into two cavities for the two testes. The dartos is continuous around the base of the scrotum with the common superficial fascia of the abdomen and perineum.

The Spermatic cord is the medium of communication between the testes and the interior of the abdomen; it is composed of arteries, veins, lymphatics, nerves, the excretory duct of the testicle and investing tunics. It commences at the internal abdominal ring, where the vessels of which it is composed converge, and passes obliquely along the spermatic canal; the cord then escapes at the external abdominal ring and descends through the scrotum to the posterior border of the testicle. The left cord is somewhat longer than the right, and permits the left testicle to reach a lower level than its fellow.

The Arteries of the spermatic cord are the spermatic artery from the aorta; the deferential artery, accompanying the vas deferens, from the superior vesical; and the cremasteric branch from the epigastric artery. The spermatic veins form a plexus, which constitutes the chief bulk of the cord; they are provided with valves at short intervals, and the smaller veins have a peculiar tendril-like arrangement which has obtained for them the name of vasa pampiniformia. The lymphatics are of large size, and terminate in the lumbar glands. The nerves are the spermatic plexus, which is derived from the aortic and renal plexus, the genital branch of the genito-crural nerve, and the scrotal branch of the ilio-scrotal.

The Vas deferens, the excretory duct of the testicle, is situated along the posterior border of the cord, where it may easily be distinguished by the hard and cordy sensation which it communicates to the fingers. Its parietes are very thick and tough, and its canal extremely small and lined by the mucous membrane continued from the urethra.

The Coverings of the spermatic cord are the spermatic fascia, cremaster muscle, and fascia propria. The spermatic fascia is a prolongation of the intercolumnar fascia, derived from the borders of the external abdominal ring during the descent of the testicle in the foetus. The cremasteric covering (erythroid) is the thin muscular expansion formed by the spreading out of the fibres of the cremaster, which is likewise carried down by the testis during its descent. The fascia propria is a continuation of the infundibiliform process from the transversalis fascia which immediately invests the vessels of the cord, and is also obtained during the descent of the testis.
The Testis (testicle) is a small oblong and rounded gland, somewhat compressed upon the sides and behind, and suspended in the cavity of the scrotum by the spermatic cord.

Its position in the scrotum is oblique; so that the upper extremity is directed upwards and forwards, and a little outwards; the lower, downwards and backwards, and a little inwards; the convex surface looks forwards and downwards, and the flattened surface to which the cord is attached, backwards and upwards. Lying against its outer and posterior border is a flattened body which follows the course of the testicle, and extends from its upper to its lower extremity; this body is named, from its relation to the testis, epididymis (ἐπίδιδυμος the testicle); it is divided into a central part or body, an upper extremity or globus major, and a lower extremity, globus minor (cauda) epididymis. The globus major is situated upon the upper end of the testicle, to which it is closely adherent; the globus minor is placed at its lower end, is attached to the testis by areolar tissue, and curves upwards, to become continuous with the vas deferens. The testis is invested by three tunics, tunica vaginalis, tunica albuginea, and tunica vasculosa; and is connected to the inner surface of the dartos by a large quantity of extremely loose areolar tissue, in which fat is never deposited, but which is very susceptible of serous infiltration.

The Tunica vaginalis is a pouch of serous membrane derived from the peritoneum in the descent of the testis, and afterwards obliterated from the abdomen to within a short distance of the gland. Like other serous coverings, it is a shut sac, investing the organ, and thence reflected so as to form a bag around its circumference; hence it is divided into the tunica vaginalis propria, and tunica vaginalis reflexa.

The tunica vaginalis propria covers the surface of the tunica albuginea.

* A transverse section of the testicle. 1. The cavity of the tunica vaginalis; the most external layer is the tunica vaginalis reflexa; and that in contact with the organ, the tunica vaginalis propria. 2. The tunica albuginea. 3. The mediastinum testis, giving off numerous fibrous cords in a radiated direction to the internal surface of the tunica albuginea. The cut extremities of the vessels below the number belong to the rete testis; and those above, to the arteries and veins of the organ. 4. The tunica vasculosa, or pia mater testis. 5. One of the lobules, consisting of the convolutions of the tubuli seminiferi, and terminating by a single duct—the vas rectum. Corresponding lobules are seen between the other fibrous cords of the mediastinum. 6. Section of the epididymis.
and surrounds the epididymis, connecting it to the testis by means of a distinct duplicature. The tunica vaginalis reflexa is attached by its external surface, through the medium of a quantity of loose areolar tissue, to the inner surface of the dartos. Between the two layers is the smooth surface of the shut sac, moistened by its proper secretion.

The Tunica albuginea (dura mater testis) is a thick fibrous membrane of a bluish white colour, and the proper tunic of the testicle. It is adherent externally to the tunica vaginalis propria, and from the union of a serous with a fibrous membrane is considered a fibro-serous membrane, like the dura mater and pericardium. After surrounding the testicle, the tunica albuginea is reflected from its posterior border into the interior of the gland, and forms a projecting longitudinal ridge, which is called the mediastinum testis (corpus Highmorianum*), from which numerous fibrous cords (trabeculae, septula) are given off, to be inserted into the inner surface of the tunic. The mediastinum serves to contain the vessels and ducts of the testicle in their passage into the substance of the organ, and the fibrous cords are admirably fitted, as has been shewn by Sir Astley Cooper, to prevent compression of the gland. If a transverse section be made of the testis, and the surface of the mediastinum examined, it will be observed that the blood-vessels of the substance of the organ are situated near the posterior border of the mediastinum, while the divided ducts of the rete testis occupy a place nearer the free margin.

The Tunica vasculosa (pia mater testis) is the nutrient membrane of the testis; it is situated immediately within the tunica albuginea, and encloses the substance of the gland, sending processes inwards between the lobules, in the same manner that the pia mater is reflected between the convolutions of the brain.

The substance of the testis consists of numerous conical flattened lobules (lobuli testis), the bases being directed towards the surface of the organ, and the apices towards the mediastinum. Krause found between four and five hundred of these lobules in a single testis. Each lobule is invested by a distinct sheath formed of two layers, one being derived from the tunica vasculosa, the other from the tunica albuginea. The lobule is composed of one or several minute tubuli, tubuli seminiferi,† exceedingly convoluted, anastomosing frequently with each other near their extremities, terminating in loops or in free caecal ends, and of the same diameter (1/15 of an inch, Lauth) throughout. The tubuli seminiferi are of a bright yellow colour; they become less convoluted in the apices of the lobules, and terminate by forming between twenty and thirty small straight ducts of about twice the dia-

* Nathaniel Highmore, a physician of Oxford, in his "Corporis Humani Disquisitio Anatomica," published in 1651, considers the corpus Highmorianum as a duct formed by the convergence of the fibrous cords, which he mistakes for smaller ducts.
† Lauth estimates the whole number of tubuli seminiferi in each testis at 840, and their average length at 2 feet 3 inches. According to this calculation, the whole length of the tubuli seminiferi would be 1890 feet.
Fig. 180.*

meter of the tubuli seminiferi, the *vasa recta*. The vasa recta enter the substance of the mediastinum, and terminate in from seven to thirteen ducts, smaller in diameter than the vasa recta. These ducts pursue a waving course from below upwards through the fibrous tissue of the mediastinum; they communicate freely with each other, and constitute the *rete testis*. At the upper extremity of the mediastinum, the ducts of the rete testis terminate in from nine to thirty small ducts, the *vasa efferentia*,† which form by their convolutions a series of conical masses, the *coni vasculosi*; from the bases of these cones tubes of larger size proceed, which constitute by their complex convolutions the body of the epididymis. The tubes become gradually larger towards the lower end of the epididymis, and terminate in a single large and convoluted duct, the vas deferens.

The *Epididymis* is formed by the convolutions of the excretory seminal ducts, external to the testis, previously to their termination in the vas deferens. The more numerous convolutions and the aggregation of the coni vasculosi at the upper end of the organ constitute the globus major; the continuation of the convolutions downwards is the body; and the smaller number of convolutions of the single tube at the lower extremity, the globus minor. The tubuli are connected together by a very delicate areolar tissue, and are enclosed by the tunica vaginalis.

A small convoluted duct, of variable length, is generally connected with the duct of the epididymis immediately before the commencement of the vas deferens. This is the vasculum aberrans of Haller; it is attached to the epididymis by the areolar tissue in which that body

† Each vas efferens with its cone measures, according to Lauth, about 8 inches. The entire length of the tubes composing the epididymis, according to the same authority, is about 21 feet.
is enveloped. Sometimes it becomes dilated towards its extremity, but more frequently retains the same diameter throughout.

The *Vas deferens* may be traced upwards in the course of the seminal fluid, from the globus minor of the epididymis along the posterior part of the spermatic cord, and along the spermatic canal to the internal abdominal ring. From the ring it is reflected inwards to the side of the fundus of the bladder, and descends along its posterior surface, crossing the direction of the ureter, to the inner border of the vesicula seminalis. In this situation it becomes somewhat larger in size and convoluted, and terminates at the base of the prostate gland, by uniting with the duct of the vesicula seminalis and constituting the ejaculatory duct. The ejaculatory duct, which is thus formed by the junction of the duct of the vesicula seminalis with the *vas deferens*, passes forwards to the anterior extremity of the veru montanum, where it terminates by opening into the prostatic urethra.

**FEMALE PELVIS.**

The peculiarities in the form of the female pelvis have already been examined with the anatomy of the bones (p. 94). Its lining boundaries are the same with those of the male. The contents are, the bladder, vagina, uterus with its appendages, and the rectum. Some portion of the small intestines also occupies the upper part of its cavity.

The *Bladder* is in relation with the *os pubis* in front, with the uterus behind, from which it is usually separated by a convolution of small intestine, and with the neck of the uterus and vagina beneath. The form of the female bladder corresponds with that of the pelvis, being broad from side to side, and often bulging more on one side than on the other. This is particularly evident after frequent parturition. The *coats* of the bladder are the same as those of the male.

The *Urethra* is about an inch and a half in length, and is lodged in the upper wall of the vagina in its course downwards and forwards, beneath the arch of the *os pubis*, to the meatus urinarius. It is lined by mucous membrane, which is disposed in longitudinal folds, and is continuous internally with that of the bladder, and externally with the vulva; the mucous membrane is surrounded by a proper coat of elastic tissue, to which the muscular fibres of the *detrusor urinae* are attached. It is to the elastic tissue that is due the remarkable dilatability of the female urethra, and its speedy return to its original diameter. The meatus is encircled by a ring of fibrous tissue, which prevents it from distending with the same facility as the rest of the canal; hence it is sometimes advantageous in performing this operation to divide the margin of the meatus slightly with the knife.

**Vagina.**—The *Vagina* is a membranous canal, leading from the vulva to the uterus, and corresponding in direction with the axis of the outlet of the pelvis. It is constricted at its commencement, but
near the uterus becomes dilated; and is closed by the contact of the anterior with the posterior wall. Its length is variable; but it is always longer upon the posterior than upon the anterior wall, the former being usually about five or six inches in length, and the latter four or five. It is attached to the cervix of the uterus, which latter projects into the upper extremity of the canal.

In Structure the vagina is composed of a mucous lining, a layer of erectile tissue, and an external tunic of contractile fibrous tissue, resembling the dartos of the scrotum. The upper fourth of the posterior wall of the vagina is covered, on its pelvic surface, by the peritoneum; while in front the peritoneum is reflected from the upper part of the cervix of the uterus to the posterior surface of the bladder. On each side it gives attachment superiorly to the broad ligaments of the uterus; and inferiorly to the pelvic fascia and levatores ani.

The Mucous membrane presents a number of transverse papillae or rugae upon its upper and lower surfaces, which extend outwards on each side from a middle raphé. The transverse papillae and raphé are more apparent upon the upper than upon the lower surface, and the two raphé are called the columns of the vagina. The mucous membrane is covered by a thin cuticular epithelium, which is continued from the labia, and terminates by a fringed border at about the middle of the cervix uteri.

The Middle or erectile layer consists of erectile tissue enclosed between two layers of fibrous membrane; this layer is thickest near the commencement of the vagina, and becomes gradually thinner as it approaches the uterus.

The External, or dartoid layer of the vagina, serves to connect it to the surrounding visceræ. Thus, it is very closely adherent to the under surface of the bladder, and drags that organ down with it in prolapsus uteri. To the rectum it is less closely connected, and that intestine is therefore less frequently affected in prolapsus.

UTERUS.

The Uterus is a flattened organ of a pyriform shape, having the base directed upwards and forwards, and the apex downwards and backwards in the line of the axis of the inlet of the pelvis, and forming a considerable angle with the course of the vagina. It is convex on its posterior surface, and somewhat flattened upon its anterior aspect. In the unimpregnated state it is about three inches in length, two in breadth across its broadest part, and one in thickness, and is divided into fundus, body, cervix, and os uteri. At the period of puberty the uterus weighs about one ounce and a half; after parturition from two to three ounces; and at the ninth month of utero-gestation from two to four pounds.

The Fundus and body are enclosed in a duplicature of peritoneum, which is connected with the two sides of the pelvis, and forms a trans-
verse septum between the bladder and rectum. The folds formed by this duplicature of peritoneum on either side of the organ are the broad ligaments of the uterus. The cervix is the lower portion of the organ; it is distinguished from the body by a well-marked constriction;

The collection of fat, forming the projection of the mons Veneris. 4. The urinary bladder. 5. The entrance of the left ureter. 6. The canal of the urethra, converted into a mere fissure by the contraction of its walls. 7. The meatus urinarius. 8. The clitoris, with its prepubis, divided through the middle. 9. The left labium majus. 10. The left labium majus. 11. The meatus of the vagina, narrowed by the contraction of its sphincter. 12. The canal of the vagina, upon which the transverse rugae are apparent. 13. The thick wall of separation between the base of the bladder and the vagina. 14. The wall of separation between the vagina and rectum. 15. The perineum. 16. The os uteri. 17. Its cervix. 18. The fundus uteri. The cavitas uteri is seen along the centre of the organ. 19. The rectum, shewing the disposition of its mucous membrane. 20. The anus. 21. The upper part of the rectum, invested by the peritoneum. 22. The recto-uterine fold of the peritoneum. 23. The utero-vesical fold. 24. The reflexion of the peritoneum, from the apex of the bladder upon the urachus to the internal surface of the abdominal parietes. 25. The last lumbar vertebra. 26. The sacrum. 27. The coccyx.
to its upper part is attached the upper extremity of the vagina, and at its extremity is an opening which is nearly round in the virgin, and transverse after parturition, the os uteri, bounded before and behind by two labia; the anterior labium being the most thick, and the posterior somewhat the longest. The opening of the os uteri is of considerable size, and is named the orificio externum; the canal then becomes narrowed, and at the upper end of the cervix is constricted into a smaller opening, the orificio internum. At this point the canal of the cervix expands into the shallow triangular cavity of the uterus, the inferior angle corresponding with the orificio internum, and the two superior angles, which are funnel-shaped, and represent the original bicorne condition of the organ, with the commencement of the Fallopian tubes. In the canal of the cervix uteri are two or three longitudinal folds, to which numerous oblique folds converge so as to give the idea of branches from the stem of a tree; hence this appearance has been denominated the arbor vita uterina. Between these folds, and around the os uteri, are numerous mucous follicles. It is the closure of the mouth of one of these follicles, and the subsequent distention of the follicle with its proper secretion, that occasions those vesicular appearances so often noticed within the mouth and cervix of the uterus, called the ovula of Naboth.

**Structure.**—The uterus is composed of three tunics; of an external or serous coat derived from the peritoneum, which constitutes the duplicatures on each side of the organ called the broad ligaments; of a middle or muscular coat, which gives thickness and bulk to the uterus; and of an internal or mucous membrane, which lines its interior, and is continuous on the one hand with the mucous lining of the Fallopian tubes, and on the other with that of the vagina. In the unimpregnated state the muscular coat is exceedingly condensed in texture, offers considerable resistance to section with the scalpel, and appears to be composed of whitish fibres inextricably interlaced and mingled with blood-vessels. In the impregnated uterus the fibres are of large size, and distinct, and are disposed in two layers, superficial and deep. The superficial layer consists of fibres which pursue a vertical direction, some being longitudinal, and others oblique. The longitudinal fibres are found principally upon the middle line, forming a thin plane upon the anterior and posterior face of the organ and upon its fundus. The oblique fibres occupy chiefly the sides and fundus. At the angles of the uterus the fibres of the superficial layer are continued outwards upon the Fallopian tubes, and into the round ligaments and ligaments of the ovaries. The deep layer consists of two hollow cones of circular fibres having their apex at the openings of the Fallopian tubes, and by their bases intermingling with each other on the body of the organ. These fibres are continuous with the deep muscular layer of the Fallopian tubes, and indicate the

* The orificio internum is not unfrequently obliterated in old persons. Indeed, this obliteration is so common, as to have induced Mayer to regard it as normal.
primitive formation of the uterus by the blending of these two canals. Around the cervix uteri the muscular fibres assume a circular form interlacing with and crossing each other at acute angles. The mucous membrane is provided with a columnar ciliated epithelium, which extends from the middle of the cervix uteri to the extremities of the Fallopian tubes.

Vessels and Nerves.—The Arteries of the uterus are the uterine from the internal iliac, and the spermatic from the aorta. The veins are very large and remarkable; in the impregnated uterus they are called sinuses, and consist of canals channeled through the substance of the organ, being merely lined by the internal membrane of the veins. They terminate on each side of the uterus in the uterine plexuses. The lymphatics terminate in the lumbar glands.

The Nerves of the uterus are derived from the hypogastric and spermatic plexuses, and from the sacral plexus. They have been made the subject of special investigation by Dr. Robert Lee, who has successfully repaired the omission made by Dr. William Hunter, in this part of the anatomy of the organ. In his numerous dissections of the uterus, both in the unimpregnated and gravid state, Dr. Lee has made the discovery of several large nervous ganglia and plexuses. The principal of these, situated on each side of the cervix uteri immediately behind the ureter, he terms the hypogastric ganglion; it receives the greater number of the nerves of the hypogastric and sacral plexus, and distributes branches to the uterus vagina, bladder, and rectum. Of the branches to the uterus, a large fasciculus proceeds upwards by the side of the organ towards its angle, where they communicate with branches of the spermatic plexus, and form another large ganglion, which he designates the spermatic ganglion, and which supplies the fundus uteri. Besides these, Dr. Lee describes vesical and vaginal ganglia, and anterior and posterior subperitoneal ganglia, and plexuses, which communicate with the preceding, and constitute an extensive nervous rete over the entire uterus. Dr. Lee concludes his observations by remarking:—“These dissections prove that the human uterus possesses a great system of nerves, which enlarges with the coats, blood-vessels, and absorbents, during pregnancy, and which returns after parturition to its original condition before conception takes place. It is chiefly by the influence of these nerves that the uterus performs the varied functions of menstruation, conception, and parturition, and it is solely by their means that the whole fabric of the nervous system sympathises with the different morbid affections of the uterus. If these nerves of the uterus could not be demonstrated, its physiology and pathology would be completely inexplicable.”

* Philosophical Transactions for 1842.
APPENDAGES OF THE UTERUS.

The Appendages of the uterus are enclosed by the lateral duplicatures of peritoneum, called the broad ligaments. They are the Fallopian tubes and ovaries.

The Fallopian* tubes or oviducts, the uterine trumpets of the French writers, are situated in the upper border of the broad ligaments, and are connected with the superior angles of the uterus. They are somewhat trumpet-shaped, being much smaller at the uterine than at the free extremity, and narrower in the middle than at either end. Each tube is about four or five inches in length, and more or less flexuous in its course. The canal of the Fallopian tube is exceedingly minute, its inner extremity opens by means of the ostium uterinum into the upper angle of the cavity of the uterus, and the opposite end into the cavity of the peritoneum. The free or expanded extremity of the Fallopian tube presents a double and sometimes a triple series of small processes or fringes, which surround the margin of the trumpet or funnel-shaped opening, the ostium abdominale. This fringe-like appendage to the end of the tube has gained for it the appellation of the frimbriated extremity; and the remarkable manner in which this circular fringe applies itself to the surface of the ovary during sexual excitement, the additional title of morsus diaboli. One of these processes, longer than the rest, or, according to Cruveilhier, a distinct ligamentous cord, is attached to the distal end of the ovary, and serves to guide the tube in its seizure of that organ.

The Fallopian tube is composed of three tunics, an external and loose investment derived from the peritoneum; a middle or muscular coat, consisting of circular [internal] and longitudinal [external] fibres, continuous with those of the uterus; and an internal or lining mucous membrane, which is continuous on the one hand with the mucous membrane of the uterus, and at the opposite extremity with the peritoneum. In the minute canal of the tube the mucous membrane is thrown into longitudinal folds or rugae, which indicate the adaptation of the tube for dilatation.

The Ovaries are two oblong flattened and oval bodies of a whitish colour, situated in the posterior layer of peritoneum of the broad ligaments. They are connected to the upper angles of the uterus at each side by means of a rounded cord, consisting chiefly of muscular fibres derived from the uterus, the ligament of the ovary.

In structure the ovary is composed of a cellulo-fibrous parenchyma or stroma, traversed by blood-vessels, and enclosed in a capsule consisting of three layers; a vascular layer, which is situated most internally and sends processes inwards to the interior of the organ; a

* Gabriel Fallopius, a nobleman of Modena, was one of the founders of modern anatomy. He was Professor at Ferrara, then at Pisa, and afterwards succeeded Vesalius at Padua. His principal observations are collected in a work, "Observationes Anatomiae," which he published in 1561.
middle or fibrous layer of considerable density, and an external investment of peritoneum. In the cells of the stroma of the ovary the small vesicles or ovisacs of the future ova, the Graafian vesicles, as they have been termed, are developed. There are usually about fifteen fully formed Graafian vesicles in each ovary; and Dr. Martin Barry has shown that countless numbers of microscopic ovisacs exist in the parenchyma of the organ, and that very few out of these are perfected so as to produce ova.

After conception a yellow spot, the *corpus luteum*, is found in one or both ovaries. The corpus luteum is a globular mass of yellow, spongy tissue, traversed by white areolar bands, and containing in its centre a small cavity, more or less obliterated, which was originally occupied by the ovum. The interior of the cavity is lined by a puckered membrane, the remains of the ovisac. In recent corpora lutea the opening by which the ovum escaped from the ovisac through the capsule of the ovary is distinctly visible; when closed, a small cicatrix may be seen upon the surface of the ovary in the situation of the opening. A similar appearance to the preceding, but of smaller size, and without a central cavity, is sometimes met with in the ovaries of the virgin; this is a *false corpus luteum*.

**Vessels and Nerves.**—The Arteries of the ovaries are the spermatic; their nerves are derived from the spermatic plexus.

The **Round Ligaments** are two muscular and fibrous cords situated between the layers of the broad ligaments, and extending from the upper angles of the uterus, and along the spermatic canals to the labia majora, in which they are lost. They are accompanied by a small artery, by several filaments of the spermatic plexus of nerves, and by a plexus of veins. The latter occasionally become varicose, and form a small tumour at the external abdominal ring which has been mistaken for inguinal hernia. The round ligaments serve to retain the uterus in its proper position in the pelvis, and during uterine gestation to draw the anterior surface of the organ against the abdominal parietes.

**EXTERNAL ORGANS OF GENERATION.**

The female organs of generation are divided into the internal and external; the internal are contained within the pelvis, and have been already described; they are the vagina, uterus, ovaries, and Fallopian tubes. The external organs are the mons Veneris, labia majora, labia minora, clitoris, meatus urinarius, and the opening of the vagina.

The **Mons Veneris** is the eminence of integument, situated upon the front of the ossa pubis. Its areolar tissue is loaded with adipose substance, and the surface covered with hairs.

The **Labia majora** are two large longitudinal folds of integument, consisting of fat and loose areolar tissue. They enclose an elliptical fissure, the common urino-sexual opening or *vulva*. The vulva re-
ceives the inferior opening of the urethra and vagina, and is bounded anteriorly by the commissura superior, and posteriorly by the commissura inferior. Stretching across the posterior commissure is a small transverse fold, the *frænum labiorum* or fourchette, which is ruptured during parturition, and immediately within this fold is a small cavity, the *fossa navicularis*. The breadth of the perineum is measured from the posterior commissure to the margin of the anus, and is usually not more than an inch across. The external surface of the labia is covered with hairs; the inner surface is smooth, and lined by mucous membrane, which contains a number of sebaceous follicles, and is covered by a thin cuticular epithelium. The use of the labia majora is to favour the extension of the vulva during parturition; for, in the passage of the head of the foetus, the labia are completely unfolded and effaced.

The *Labia minora*, or *nymphae*, are two smaller folds situated within the labia majora. Superiorly they are divided into two processes, which surround the glans clitoridis, the superior fold forming the praæputium clitoridis, and the inferior its *frænum*. Inferiorly, they diminish gradually in size, and are lost on the sides of the opening of the vagina. The *nymphae* consist of mucous membrane, covered by a thin cuticular epithelium. They are provided with a number of sebaceous follicles, and contain, in their interior, a layer of erectile tissue.

The *Clitoris* is a small elongated organ situated in front of the os pubis, and supported by a suspensory ligament. It is formed by a small body, which is analogous to the corpus cavernosum of the penis, and, like it, arises from the ramus of the os pubis and ischium on each side, by two *crura*. The extremity of the clitoris is called its *glans*. It is composed of erectile tissue, enclosed in a dense layer of fibrous membrane, and is susceptible of erection. Like the penis, it is provided with two small muscles, the *erectores clitoridis*.

At about an inch beneath the clitoris is the entrance of the vagina, an elliptical opening, marked by a projecting margin. The entrance to the vagina is closed in the virgin by a membrane of a semilunar form, which is stretched across the opening; this is the *hymen*. Sometimes the membrane forms a complete septum, and gives rise to great inconvenience by preventing the escape of the menstrual effusion. It is then called an *imperforate hymen*. The *hymen* must not be considered a necessary accompaniment of virginity, for its existence is very uncertain. When present it assumes a variety of appearances: it may be a membranous fringe, with a round opening in the centre, or a semilunar fold, leaving an opening in front; or a transverse septum, having an opening both in front and behind; or a vertical band with an opening at either side.

The rupture of the hymen or its rudimentary existence, gives rise to the appearance of a fringe of papillæ around the opening of the vagina: these are called *carunculae myrtiformes*.

The triangular smooth surface between the clitoris and the entrance
of the vagina, which is bounded on each side by the upper portions
the nymphae, is the vestibule.

At the upper angle of the vagina is an elevation formed by the pro-
jection of the upper wall of the canal, and analogous to the bulb
of the urethra of the male: and immediately in front of this tubercle,
and surrounded by it, is the opening of the urethra, the meatus
urinarius.

MAMMARY GLANDS.

The Mammae are situated in the pectoral region; and are separated
from the pectoralis major muscle by a thin layer of superficial fascia.
They exist in the male as well as in the female, but in a rudimentary
state, unless excited into growth by some peculiar action, such as the
loss or atrophy of the testes.

Their base is somewhat elliptical, the long diameter corresponding
with the direction of the fibres of the pectoralis major muscle; and the
left mamma is generally a little larger than the right.

Near the centre of the convexity of each mamma is a small pro-
jection of the integument, called the nipple, which is surrounded by an
areola having a coloured tint. In the female before impregnation,
the colour of the areola is a delicate pink; after impregnation it assumes a
brownish hue, which deepens in colour as pregnancy advances; and
after the birth of a child, the brownish tint continues through life.

The areola is furnished with a considerable number of sebaceous
follicles, which secrete a peculiar fatty substance for the protection of
the delicate integument around the nipple. During suckling these
follicles are increased in size, and have the appearance of small
pimplies, projecting from the skin. At this period they serve by their
increased secretion to defend the nipple and areola from the excoriating
action of the saliva of the infant.

In Structure, the mamma is a conglomerate gland, and consists of
lobes, which are held together by a dense and firm areolar tissue; the
lobes are composed of lobules; and the lobules, of minute caecal
vesicles, the ultimate terminations of the excretory ducts.

The excretory ducts (tubuli lactiferi), from ten to fifteen in number,
commence by small openings at the apex of the nipple, and pass
inwards, parallel with each other, towards the central part of the gland,
where they form dilatations (ampullae), and give off numerous branches
to ramify through the gland to their ultimate terminations in the
minute lobules.

The ducts and caecal vesicles are lined throughout by a mucous
membrane, which is continuous at the apex of the nipple with the
integument.

In the nipple the excretory ducts are surrounded by a tissue ana-
logous to the dartos of the scrotum, to which the power of erectility of
the nipple seems due. There is no appearance of any structure re-
sembling erectile tissue.
Vessels and Nerves.—The mammae are supplied with arteries from the thoracic branches of the axillary, from the intercostals, and from the internal mammary.

The Lymphatics follow the border of the pectoralis major to the axillary glands.

The Nerves are derived from the thoracic and intercostals.
CHAPTER XI.

ANATOMY OF THE FŒTUS.

The medium weight of a child of the full period, at birth, is seven pounds, and its length seventeen inches; the extremes of weight are four pounds and three quarters, and ten pounds, and the extremes of measurement fifteen and twenty inches. The head is of large size, and lengthened from before backwards; the face small. The upper extremities are greatly developed, and the thorax expanded and full. The upper part of the abdomen is large, from the great size of the liver; the lower part is small and conical. And the lower extremities are very small in proportion to the rest of the body. The external genital organs are very large, and fully developed, and the attachment of the umbilicus is one inch farther from the vertex of the head than from the soles of the feet; and one inch farther from the ensiform cartilage than the symphysis pubis.

**OSSEOUS SYSTEM.**—The development of the osseous system has been treated of in the first Chapter. The ligamentous system presents no peculiarity deserving of remark.

**MUSCULAR SYSTEM.**—The muscles of the fœtus at birth are large and fully formed. They are of a lighter colour than those of the adult, and of a softer texture. The transverse striae upon the fibres of animal life are not distinguishable until the sixth month of fetal life.

**VASCULAR SYSTEM.**—The circulating system presents several peculiarities; 1stly, In the heart; there is a communication between the two auricles by means of the foramen ovale. 2dly, In the arterial system; there is a communication between the pulmonary artery and descending aorta, by means of a large trunk, the ductus arteriosus. 3dly, Also in the arterial system; the internal iliac arteries, under the number of hypogastric and umbilical, are continued from the fœtus to the placenta, to which they return the blood which has circulated in the system of the fœtus. 4thly, In the venous system; there is a communication between the umbilical vein and the inferior vena cava, called the ductus venosus.

**FŒTAL CIRCULATION.**

The pure blood is brought from the placenta by the umbilical vein. The umbilical vein passes through the umbilicus and enters the liver, where it divides into several branches, which may be arranged under three heads:—1stly, Two or three, which are distributed to the left
The fœtal circulation. 1. The umbilical cord, consisting of the umbilical vein and two umbilical arteries; proceeding from the placenta (2). 3. The umbilical vein dividing into three branches; two (4, 4) to be distributed to the liver; and one (5), the ductus venosus, which enters the inferior vena cava (6). 7. The portal vein, returning the blood from the intestines, and uniting with the right hepatic branch. 8. The right auricle; the course of the blood is denoted by the arrow, proceeding from 8, to 9, the left auricle. 10. The left ventricle; the blood following the arrow to the arch of the aorta (11), to be distributed through the branches given off by the arch to the head and upper extremities. The arrows 12 and 13, represent the return of the blood from
lobe. 2dly, A single branch, which communicates with the portal vein in the transverse fissure, and supplies the right lobe. 3dly, A large branch, the ductus venosus, which passes directly backwards, and joins the inferior cava. In the inferior cava the pure blood becomes mixed with that which is returning from the lower extremities, and is carried through the right auricle, guided by the Eustachian valve, and through the foramen ovale into the left auricle. From the left auricle it passes into the left ventricle, and from the left ventricle into the aorta, whence it is distributed, by means of the carotid and subclavian arteries, principally to the head and upper extremities. From the head and upper extremities, the impure blood is returned by the superior vena cava to the right auricle; from the right auricle, it is propelled into the right ventricle; and from the right ventricle into the pulmonary artery. In the adult, the blood would now be circulated through the lungs, and oxygenated; but in the foetus the lungs are solid, and almost impervious. Only a small quantity of the blood passes therefore into the lungs; the greater part rushes through the ductus arteriosus, into the commencement of the descending aorta, where it becomes mingled with that portion of the pure blood which is not sent through the carotid and subclavian arteries.

Passing along the aorta, a small quantity of this mixed blood is distributed by the external iliac arteries to the lower extremities; the greater portion is conveyed by the internal iliac, hypogastric, and umbilical arteries to the placenta; the hypogastric arteries proceeding from the internal iliacs, and passing by the side of the fundus of the bladder, and upwards along the anterior wall of the abdomen to the umbilicus, where they become the umbilical arteries.

From a careful consideration of this circulation, we shall perceive—
1st. That the pure blood from the placenta is distributed in considerable quantity to the liver, before entering the general circulation. Hence arises the abundant nutrition of that organ, and its enormous size in comparison with the other viscera.

2dly. That the right auricle is the scene of meeting of a double current; the one coming from the inferior cava, the other from the superior, and that they must cross each other in their respective course. How this crossing is effected the theorist will wonder; not so the practical anatomist; for a cursory examination of the foetal heart will show, 1. That the direction of entrance of the two vessels is so oppo-

the head and upper extremities through the jugular and subclavian veins, to the superior vena cava (14), to the right auricle (8), and in the course of the arrow through the right ventricle (15), to the pulmonary artery (16). 17. The ductus arteriosus, which appears to be a proper continuation of the pulmonary artery, the offsets at each side are the right and left pulmonary artery cut off; these are of extremely small size as compared with the ductus arteriosus. The ductus arteriosus joins the descending aorta (18, 19), which divides into the common iliacs, and these into the internal iliacs, which become the hypogastric arteries (19), and return the blood along the umbilical cord to the placenta; while the other divisions, the external iliacs (20), are continued into the lower extremities. The arrows at the terminations of these vessels mark the return of the venous blood by the veins to the inferior cava.
site, that they may discharge their currents through the same cavity without admixture. 2. That the inferior cava opens almost directly into the left auricle. 3. That by the aid of the Eustachian valve, the current in the inferior cava will be almost entirely excluded from the right ventricle.

3dly. That the blood which circulates through the arch of the aorta comes directly from the placenta; and, although mixed with the impure blood of the inferior cava, yet is propelled in so great abundance to the head and upper extremities, as to provide for the increased nutrition of those important parts, and prepare them, by their greater size and development, for the functions which they are required to perform at the instant of birth.

4thly. That the blood circulating in the descending aorta is very impure, being obtained principally from the returning current in the superior cava; a small quantity only being derived from the left ventricle. Yet is it from this impure blood that the nutrition of the lower extremities is provided. Hence we are not surprised at their insignificant development at birth; while we admire the providence of nature, that directs the nutrient current in abundance to the organs of sense, of prehension, and of deglutition, so necessary even at the instant of birth to the safety and welfare of the creature.

After birth, the foramen ovale becomes gradually closed by a membranous layer, which is developed from the margins of the opening from below upwards, and completely separates the two auricles. The situation of the foramen is seen in the adult heart, upon the septum auricularum, and is called the fossa ovalis; the projecting margin of the opening is the annulus ovalis.

As soon as the lungs have become inflated by the first act of inspiration, the blood of the pulmonary artery rushes through its right and left branches into the lungs, to be returned to the left auricle by the pulmonary veins. Thus the pulmonary circulation is established. Then the ductus arteriosus contracts, and degenerates into an impervious fibrous cord, serving in after life merely as a bond of union between the left pulmonary artery and the concavity of the arch of the aorta.

The current through the umbilical cord being arrested, the umbilical arteries likewise contract and become impervious, and degenerate into the umbilical ligaments of the bladder.

The umbilical vein and ductus venosus, also deprived of their circulating current, become reduced to fibrous cords, the former being the round ligament of the liver, and the latter a fibrous band which may be traced along the fissure for the ductus venosus to the inferior vena cava.

Nervous system.—The brain is very soft, almost pulpy, and has a reddish tint throughout; its weight at birth, relatively to the entire body, is as one to six, and the difference between the white and grey substance is not well marked. The nerves are firm and well developed.
ORGANS OF SENSE.

Eye.—The eyeballs are of large size and well developed at birth. The pupil is closed by a vascular membrane called the *membrana pupillaris*, which disappears at about the seventh month. Sometimes it remains permanently, and produces blindness. It consists of two thin membranous layers, between which the ciliary arteries are prolonged from the edge of the iris, and form arches and loops by returning to it again, without anastomosing with those of the opposite side. The removal of the membrane takes place by the contraction of these arches and loops towards the edge of the pupil. The capsule of the lens is extremely vascular.

Ear.—The ear is remarkable for its early development; the labyrinth and ossicula auditus are ossified at an early period, and the latter are completely formed before birth. The only parts remaining incomplete are the mastoid cells, and the meatus auditorius. The *membrana tympani* in the foetal head is very oblique, occupying almost the basilar surface of the skull; hence probably arises a deficient acuteness in the perception of sound. It is also extremely vascular.

Nose.—The sense of smell is very imperfect in the infant, as may be inferred from the small capacity of the nasal fossae, and the non-development of the ethmoid, sphenoid, frontal, and maxillary sinuses.

THYROID GLAND.

The *Thyroid gland* is of large size in the foetus, and is developed by two lateral halves, which approach and become connected at the middle line so as to constitute a single gland. It is doubtful whether it performs any especial function in foetal life.

THYMUS GLAND.

The *Thymus gland* consists of a thoracic and a cervical portion on each side. The former is situated in the anterior mediastinum, and the latter is placed in the neck just above the first bone of the sternum, and behind the sterno-hyoid and sterno-thyroid muscles." It extends upwards from the fourth rib as high as the thyroid gland, resting upon the pericardium, and separated from the arch of the aorta and great vessels by the thoracic fascia in the chest, and lying on each side of the trachea in the neck.

Although described usually as a single gland, it consists actually of

* In the description of this gland I have adhered closely to the history of it given by Sir Astley-Cooper, in his beautiful monograph "On the Anatomy of the Thymus Gland," 1832.
two lateral, almost symmetrical glands, connected with each other by areolar tissue only, and having no structural communication: they may therefore be "properly called a right and left thymus gland."

Between the second and third months of embryo existence, the thymus is so small as to be only "just perceptible"; and continues gradually increasing with the growth of the fetus until the seventh. At the eighth month it is large; but, during the ninth, it undergoes a sudden change, assumes a greatly increased size, and at birth weighs 240 grains. After birth it continues to enlarge until the expiration of the first year, when it ceases to grow, and gradually diminishes, until at puberty it has almost disappeared.

The thymus is a conglomerate gland, being composed of lobules disposed in a spiral form around a central cavity. The lobules are held together by a firm areolar tissue ("reticulated"), and the entire gland is enclosed in a coarse areolar capsule.

*Fig. 183.*

The *Lobules* are very numerous, and vary in size from that of the head of a pin to a moderate-sized pea. Each lobule contains in its interior a small cavity, or "secretory cell," and several of these cells

* A section of the thymus gland at the eighth month, shewing its anatomy. This figure, and the succeeding, were drawn from two of Sir Astley Cooper's beautiful preparations, with the kind permission of their possessor. The references were made by Sir Astley's own hand. 1. The cervical portions of the gland; the independence of the two lateral glands is well marked. 2. Secretory cells seen upon the cut surface of the section; these are observed in all parts of the section. 3, 3. The pores or openings of the secretory cells and pouches; they are seen dispersed upon the whole internal surface of the great central cavity or reservoir. The continuity of the reservoir in the lower or thoracic portion of the gland, with the cervical portion, is seen in the figure.
open into a small "pouch" which is situated at their base, and leads to the central cavity, the "reservoir of the thymus."

The Reservoir is lined in its interior by a vascular mucous membrane, which is raised into ridges by a layer of ligamentous bands situated beneath it. The ligamentous bands proceed in various directions, and encircle the open mouths (pores) of the secretory cells and pouches. This ligamentous layer serves to keep the lobules together, and prevent the injurious distension of the cavity.

When either gland is carefully unravelled by removing the areolar capsule and vessels, and dissecting away the reticulated areolar tissue which retains the lobules in contact, the reservoir, from being folded in a serpentine manner upon itself, admits of being drawn out into a lengthened tubular cord,† around which the lobules are clustered in a spiral manner, and resemble knots upon a cord, or a string of beads.

The reservoir, pouches, and cells, contain a white fluid "like chyle," or "like cream, but with a small admixture of red globules."

In an examination of the thymic fluid which I lately made, with a Powell microscope magnifying 600 times linear measure, I observed that the corpuscles were very numerous, smaller than the blood particles, globular and oval in form, irregular in outline, variable in size, and provided with a small central nucleus.

In the human foetus this fluid has been found by Sir Astley in too

* The course and termination of the "absorbent ducts" of the thymus of the calf; from one of Sir Astley Cooper's preparations. 1. The two internal jugular veins. 2. The superior vena cava. 3. The thoracic duct, dividing into two branches, which reunite previously to their termination in the root of the left jugular vein. 4. The two thymic ducts; that on the left side opens into the thoracic duct, and that on the right into the root of the right jugular vein.

† See the beautiful plates in Sir Astley Cooper's work.
small proportion to be submitted to chemical analysis. But the thymic fluid of the fetal calf, which exists in great abundance, gave the following analytical* results: one hundred parts of the fluid contained sixteen parts of solid matter, which consisted of,

- Incipient fibrine,
- Albumen,
- Mucus, and muco-extractive matter,
- Muriate and phosphate of potass,
- Phosphate of soda,
- Phosphoric acid, a trace.

The Arteries of the thymus gland are derived from the internal mammary, and from the superior and inferior thyroid.

The Veins terminate in the left vena innominata, and some small branches in the thyroid veins.

The Nerves are very minute, and are derived chiefly through the internal mammary plexus, from the superior thoracic ganglion of the sympathetic. Sir Astley Cooper has also seen a branch from the junction of the pneumogastric and sympathetic pass to the side of the gland.

The Lymphatics terminate in the general union of the lymphatic vessels at the junction of the internal jugular and subclavian veins. Sir Astley Cooper has injected them only once in the human foetus, but in the calf he finds two large lymphatic ducts, which commence in the upper extremities of the glands, and pass downwards, to terminate at the junction of the jugular and subclavian vein at each side. These vessels he considers the "absorbent ducts of the glands; 'thymic ducts';" they are the carriers of the fluid from the thymus into the veins."

Sir Astley Cooper concludes his anatomical description of this gland with the following interesting physiological observations:—

"As the thymus secretes all the parts of the blood, viz. albumen, fibrine, and particles, is it not probable that the gland is designed to prepare a fluid well fitted for the fetal growth and nourishment from the blood of the mother, before the birth of the foetus, and, consequently, before chyle is formed from food?—and this process continues for a short time after birth, the quantity of fluid secreted from the thymus gradually declining as that of chylification becomes perfectly established."

FETAL LUNGS.

The Lungs, previously to the act of inspiration, are dense and solid in structure, and of a deep red colour. Their specific gravity is greater than water, in which they sink to the bottom; whereas lung which has

* This analysis was conducted by Dr. Dowler of Richmond.
respired will float upon that fluid. The specific gravity is, however, no test of the real weight of the lung, the respired lung being actually heavier than the fœtal. Thus the weight of the fœtal lung, at about the middle period of uterine life, is to the weight of the body as 1 to 60.* But, after respiration, the relative weight of the lung to the entire body is as 1 to 30.

FETAL HEART.

The Heart of the fœtus is large in proportion to the size of the body; it is also developed very early, representing at first a simple vessel, and undergoing various degrees of complication until it arrives at the compound character which it presents after birth. The two ventricles form, at one period, a single cavity, which is afterwards divided into two by the septum ventriculorum. The two auricles communicate up to the moment of birth, the septum being incomplete, and leaving a large opening between them, the foramen ovale (foramen of Botal†).

The Ductus arteriosus is another peculiarity of the fœtus connected with the heart; it is a communication between the pulmonary artery and the aorta. It degenerates into a fibrous cord after birth, from the double cause of a diversion in the current of the blood towards the lungs, and from the pressure of the left bronchus, caused by its distension with air.

VISCERA OF THE ABDOMEN.

At an early period of uterine life, and sometimes at the period of birth, as I have twice observed in the imperfectly developed fœtus, two minute fibrous threads may be seen passing from the umbilicus to the mesentery. These are the remains of the omphalo-mesenteric vessels.

The Omphalo-mesenteric are the first developed vessels of the germ: they ramify upon the vesicula umbilicalis, or yolk-bag, and supply the newly formed alimentary canal of the embryo. From them, as from a centre, the general circulating system is produced. After the establishment of the placental circulation they cease to carry blood, and dwindle to the size of mere threads, which may be easily demonstrated in the early periods of uterine life; but are completely removed, excepting under peculiar circumstances, at a later period.

The Stomach is of small size, and the great extremity but little developed. It is also more vertical in direction the earlier it is examined, a position that would seem due to the enormous magnitude of the liver, and particularly of its left lobe.

The Appendix vermiformis cæci is long and of large size, and is con-

† Leonard Botal, of Piedmont, was the first of the moderns who gave an account of this opening, in a work published in 1565. His description is very imperfect. The foramen was well known to Galen.
continued directly from the central part of the cul-de-sac of the cæcum, of which it appears to be a constricted continuation. This is the character of the appendix cæci in the higher quadrumanæ.

The large intestines are filled with a dark green viscous secretion, called meconium (μέκων, poppy), from its resemblance to the inspissated juice of the poppy.

The Pancreas is comparatively larger in the foetus than in the adult.

The Spleen is comparatively smaller in the foetus than in the adult.

**Fœtal Liver.**

The Liver is the first formed organ in the embryo. It is developed from the alimentary canal, and, at about the third week, fills the whole abdomen, and is one-half the weight of the entire embryo. At the fourth month the liver is of immense size in proportion to the bulk of the foetus. At birth it is of very large size, and occupies the whole upper part of the abdomen. The left lobe is as large as the right, and the falciform ligament corresponds with the middle line of the body. The liver diminishes rapidly after birth, probably from obliteration of the umbilical vein.

**Kidneys and Supra-renal Capsules.**

The Kidneys present a lobulated appearance in the foetus, which is their permanent type amongst some animals, as the bear, the otter, and cetacea.

The Supra-renal capsules are organs which appear, from their early and considerable development, to belong especially to the economy of the foetus. They are distinctly formed at the second month of embryonic life, and are greater in size and weight than the kidneys. At the third or fourth month they are equalled in bulk by the kidneys; and at birth they are about one-third less than those organs.

**Viscera of the Pelvis.**

The Bladder in the foetus is long and conical, and is situated altogether above the upper border of the os pubis, which is as yet small and undeveloped. It is, indeed, an abdominal viscus, and is connected superiorly with a fibrous cord, called the urachus, of which it appears to be an expansion.

The Urachus is continued upwards to the umbilicus, and becomes connected with the umbilical cord. In animals it is a pervious duct, and is continuous with one of the membranes of the embryo, the allantois. It has been found pervious in the human foetus, and the
The Testes.

urine has been passed through the umbilicus. Calculous concretions have also been found in its course.

The Uterus, in the early periods of embryonic existence, appears bifid, from the large size of the Fallopian tubes, and the small development of the body of the organ. At the end of the fourth month the body assumes a larger bulk, and the bifid appearance is lost. The cervix uteri in the fetus is larger than the body of the organ.

The Ovaries are situated, like the testicles, in the lumbar region, near the kidneys, and descend from thence gradually into the pelvis.

TESTES.

The Testicles in the embryo are situated in the lumbar regions, immediately in front of and somewhat below the kidneys. They have connected with them inferiorly a peculiar structure which assists in their descent, and is called the gubernaculum testis.

The Gubernaculum is a soft and conical cord composed of areolar tissue containing in its areolae a gelatiniform fluid. In the abdomen it lies in front of the psoas muscle, and passes along the spermatic canal, which it serves to distend for the passage of the testis. It is attached by its superior and larger extremity to the lower end of the testis and epididymis, and by the inferior extremity to the bottom of the scrotum. The gubernaculum is surrounded by a thin layer of muscular fibres, the cremaster, which pass upwards upon this body to be attached to the testis. Inferiorly the muscular fibres divide into three processes, which, according to Mr. Curling,* are thus attached:—"The external and broadest is connected to Poupart's ligament in the inguinal canal; the middle forms a lengthened band, which escapes at the external abdominal ring, and descends to the bottom of the scrotum, where it joins the dartos; the internal passes in the direction inwards, and has a firm attachment to the os pubis and sheath of the rectus muscle. Besides these a number of muscular fibres are reflected from the internal oblique on the front of the gubernaculum."

The Descent of the testicle is gradual and progressive. Between the fifth and sixth months it has reached the lower part of the psoas muscle, and during the seventh it makes its way through the spermatic canal, and descends into the scrotum.

While situated in the lumbar region, the testis and gubernaculum are placed behind the peritoneum, by which they are invested upon their anterior surface and sides. As they descend, the investing peritoneum is carried downwards with the testis into the scrotum, forming a lengthened pouch, which by its upper extremity opens into the cavity of the peritoneum. The upper part of this pouch being compressed by the spermatic canal is gradually obliterated, the obliteration extending

downwards along the spermatic cord nearly to the testis. That portion of the peritoneum which immediately surrounds the testis is, by the above process, cut off from its continuity with the peritoneum, and is termed the tunica vaginalis; and as this membrane must be obviously

a shut sac, one portion of it investing the testis, and the other being reflected so as to form a loose bag around it, its two portions have received the appellations of tunica vaginalis propria, and tunica vaginalis reflexa.

The descent of the testis is effected by means of the traction of the muscle of the gubernaculum (cremaster). "The fibres," writes Mr. Curling,† "proceeding from Poupart's ligament and the obliquus internus, tend to guide the gland into the inguinal canal; those attached to the os pubis, to draw it below the abdominal ring; and the process descending to the scrotum, to direct it to its final destination." During the descent "the muscle of the testis is gradually everted, until, when the transition is completed, it forms a muscular envelope external to the process of peritoneum, which surrounds the gland and the front of the cord." "The mass composing the central part of the

* A diagram illustrating the descent of the testis. 1. The testis. 2. The epididymis. 3. 3. The peritoneum. 4. The pouch formed around the testis by the peritoneum, the future cavity of the tunica vaginalis. 5. The pubic portion of the cremaster attached to the lower part of the testis. 6. The portion of the cremaster attached to Poupart's ligament. The mode of eversion of the cremaster is shewn by these lines. 7. The gubernaculum, attached to the bottom of the scrotum, and becoming shortened by the contraction of the muscular fibres which surround it. 8. 8. The cavity of the scrotum.

† In this figure the testis has completed its descent. The gubernaculum is shortened to its utmost, and the cremaster completely everted. The pouch of peritoneum above the testis is compressed so as to form a tubular canal. 1. A dotted line marks the point at which the tunica vaginalis will terminate superiorly; and the figure 2 its cavity. 3. The peritoneal cavity.

‡ Loc. cit.
gubernaculum, which is so soft, lax, and yielding as in every way to facilitate these changes, becomes gradually diffused, and, after the arrival of the testicle in the scrotum, contributes to form the loose cellular tissue which afterwards exists so abundantly in this part."

The attachment of the gubernaculum to the bottom of the scrotum is indicated throughout life by distinct traces.
